GNU poke is an interactive, extensible editor for binary data. Not limited to editing basic entities such as bits and bytes, it provides a full-fledged procedural, interactive programming language designed to describe data structures and to operate on them.

This manual describes the `poke` binary data editor as well as the Poke language.
1 Introduction

1.1 Motivation

The main purpose of GNU poke is to manipulate structured binary data in terms of abstractions provided by the user. The Poke type definitions can be seen as a sort of declarative specifications for decoding and encoding procedures. The user specifies the structure of the data to be manipulated, and poke uses that information to automagically decode and encode the data. Under this perspective, struct types correspond to sequences of instructions, array types to repetitions or loops, union types to alternatives or conditionals, and so on.

1.1.1 Decode-Compute-Encode

Computing with data whose form is not the most convenient way to be manipulated, like is often the case in unstructured binary data, requires performing a preliminary step that transforms the data into a more convenient representation, usually featuring a higher level of abstraction. This step is known in computer jargon as unmarshalling, when the data is fetched from some storage or transmission media or, more generally, decoding.

Once the computation has been performed, the result should be transformed back to the low-level representation to be stored or transmitted. This is performed in a closing step known as marshalling or, more generally, encoding.

Consider the following C program whose purpose is to read a 32-bit signed integer from a byte-oriented storage media at a given offset, multiply it by two, and store the result at the same offset.

```c
void double_number (int fd, off_t offset, int endian)
{
    int number, i;
    unsigned char b[4];

    /* Decode. */
    lseek (fd, offset, SEEK_SET);
    for (i = 0; i < 4; ++i)
        read (fd, &b[i], 1);

    if (endian == BIG)
    else

    /* Compute. */
    number = number * 2;

    /* Encode. */
    if (endian == BIG)
    {
        b[0] = (number >> 24) & 0xff;
        b[1] = (number >> 16) & 0xff;
        b[2] = (number >> 8) & 0xff;
        b[3] = number & 0xff;
    }
    else
    {
```
As we can see, decoding takes care of fetching the data from the storage in simple units, bytes. Then it mounts the more abstract entity on which the computation will be performed, in this case a signed 32-bit integer. Considerations like endianness, negative encoding (which is assumed to be two’s complement in this example and handled automatically by C) and error conditions (omitted in this example for clarity) should be handled properly.

Conversely, encoding turns the signed 32-bit integer into a sequence of bytes and then writes them out to the storage at the desired offset. Again, this requires taking endianness into account and handling error conditions.

This example may look simplistic and artificial, and it is, but too often the computation proper (like multiplying the integer by two) is way more straightforward than the decoding and encoding of the data used for the computation.

Generally speaking, decoding and encoding binary data is laborious and error prone. Think about sequences of elements, variable-length and clever compact encodings, elements not aligned to byte boundaries, the always bug-prone endianness, and a long etc. Dirty business, sometimes risky, and always boring.

1.1.2 Describe-Compute

This is where poke comes into play. Basically, it allows you to describe the characteristics of the data you want to compute on, and then decodes and encodes it for you, taking care of the gory details. That way you can concentrate your energy on the fun part: computing on the data at your pleasure.

Of course, you are still required to provide a description of the data. In the Poke language, these descriptions take the form of type definitions, which are declarative: you specify what you want, and poke extracts the how from that.

For example, consider the following Poke type definition:

```pke
type Packet =
  struct
  { 
    uint<16> magic == 0xef;
    uint<32> size;
    byte[size] data @ 8#B;
  };
```

This tells poke that, in order to decode a Packet, it should perform the following procedure (a similar procedure is implied for encoding):

- Read two bytes from the IO space, mount them into an unsigned 16-bit integer using whatever current endianness, and put it in magic. If this unsigned 16-bit integer doesn’t equal to 0xef, then stop and emit a “data integrity” error.
- Read four bytes, mount them into an unsigned 32-bit integer using the same endianness, and put it in size.
Seek the IO space to advance 16 bits.

Do size times:
  - Read one byte and mount it into an unsigned 8-bit integer.
  - Put the integer in the proper place in the data array.

If during this procedure an end of file is encountered, or some other erroneous condition happens, an appropriate error is raised.

In the procedure sketched above we find a sequence of operations, implied by the struct type, and a loop, implied by the array type. As we shall see later in this book, it is also possible to decode conditionally. Union types are used for that purpose.

1.2 Nomenclature

GNU poke is a new program and it introduces many new concepts. It is a good idea to clarify how we call things in the poke community. Unless everyone uses the same nomenclature to refer to pokish thingies, it is gonna get very confusing very soon!

First of all we have poke, the program. Since “poke” is a very common English word, when the context is not clear we either use the full denomination GNU poke, or quote the word using some other notation.

Then we have Poke, with upper case P, which is the name of the domain-specific programming language implemented by poke, the program.

This distinction is important. For example, when people talk about “poke programmers” they refer to the group of people hacking GNU poke. When they talk about “Poke programmers” they refer to the people who write programs using the Poke programming language.

Finally, a pickle is a Poke source file containing definitions of types, variables, functions, etc, that conceptually apply to some definite domain. For example, elf.pk is a pickle that provides facilities to poke ELF object files. Pickles are not necessarily related to file formats: a set of functions to work with bit patterns, for example, could be implemented in a pickle named bitpatterns.pk.

We hope this helps to clarify things.

1.3 Invoking poke

Synopsis:

```
poke [option... ] [file]
```

The following options are available.

'-'l'
 loạn=file'

Load the given file as a Poke program. Any number of 'l' options can be specified, and they are loaded in the given order.

'-'L file'

Load the given file as a Poke program and exit. The rest of the command-line is not processed by poke, and is available to the Poke script in the argv variable. This is commonly used along with a shebang (see Section 1.4.5 [Scripts], page 8) to implement Poke scripts.

Commanding poke from the command line:

'-'c'
 loạn=cmd'

Execute the given command. Any number of 'c' options can be specified, and they are executed in the given order.
'--s'
'--source=file'

Load file as a command file. Any number of 's' options may be specified, and they are loaded in the given order. See Section 1.4.4 [Command Files], page 8.

Styling text output:
'--color=how'
Whether to use styled output, and how. Valid options for how are 'yes', 'no', 'auto', 'html' and 'test'.

'--style-dark'
Use the default style that works better for dark backgrounds. This is the default.

'--style-bright'
Use the default style that works better for bright backgrounds.

'--style=file'
Use file as the CSS to use for styling poke, instead of the default style.

Other options:
-q
--no-init-file
Do not load the ~/.pokerc init file.

--no-auto-map
Do not load map-files automatically when poke opens IO spaces.

--no-hserver
Do not run the terminal hyperlinks server.

--no-stdtypes
Do not define standard Poke types (such as int, char, etc) in the Poke incremental compiler.

--quiet
Be as terse as possible.

--help
Print a help message and exit.

--version
Show version and exit.

The following environment variables, if set, are used by poke:

POKE_LOAD_PATH
List of file paths separated by the colon characters (:) which is prepended to the load_path when poke starts.

1.4 Commanding poke

GNU poke is primarily an interactive editor that works in the command line. However, it is also possible to use it in a non-interactive way. This chapter documents both possibilities.

1.4.1 The REPL

If poke is invoked with an interactive TTY connected to the standard input, it greets you with a welcome message, licensing information and such, and finally a prompt that looks like:

(poke)

At this point, the program is ready to be commanded. You are expected to introduce a line and press enter. At that point poke will examine the command, notify you if there is some error condition, process the line and maybe displaying something in the terminal.
Repeatedly typing complex commands can be tiresome. To help you, poke uses the readline library See GNU Readline Library. This provides shortcuts and simple keystrokes to repeat previous commands with or without modification, fast selection of file names and entries from other multiple choice contexts, and navigation within a command and among previous commands. When the REPL starts, the history of your previous sessions are loaded from the file .poke_history located in your home directory (if it exists).

There are several kinds of lines that can be provided in the REPL:
- A dot-command invocation, that starts with a dot character (.).
- A command invocation.
- A Poke statement.
- A Poke expression.

These are explained in the following sections.

1.4.2 Evaluation
You can evaluate a Poke statement by typing it at the REPL’s prompt. Only a single statement, including expression statements (see Section 25.12 [Expression Statements], page 172) and compound statements (see Section 25.9 [Compound Statements], page 171), can be evaluated this way. It needs not be terminated by a semicolon.

When an expression is evaluated, the result of the evaluation is printed back to you. For example:

```
(poke) 23
23
(poke) [1,2,3]
[1,2,3]
(poke) Packet @ 0#B
Packet {i=1179403647,j=65794L}
```

When a statement other than an expression statement is executed in the REPL no result is printed, but of course the statement can print on its own:

```
(poke) fun do_foo = void: {}
(poke) do_foo
(poke) for (i in [1,2,3]) printf "elem %i32d\n", i;
  elem 1
  elem 2
  elem 3
```

If there is an error compiling the line, you are notified with a nice error message, showing the location of the error. For example:

```
(poke) [1,2,3 + "foo"]
<stdin>:1:6: error: invalid operands in expression
[1,2,3 + "foo"];
```

1.4.3 Commands and Dot-Commands
There are two kinds of commands in poke: the dot-commands, which are written in C and have their own conventions for handling sub-commands and passing arguments and flags, and normal commands, which are written in Poke.

1.4.3.1 Dot-Commands
Dot-commands are so called because their names start with the dot character (.). They can feature subcommands. Example:
When there is no ambiguity, the command name and the subcommands can be shortened to prefixes. The commands above can also be written as:

(poke) .vm dis e int[] @ 0#B
(poke) .vm dis f (dump)

Some commands also get flags, which are one-letter indicators that can be appended to the command name (including subcommands) after a slash character (/). For example, the .vm disassembler commands accept a n flag to indicate we want a native disassemble. We can pass it as follows:

(poke) .vm disassemble expression/n int[] @ 0#B
(poke) .vm disassemble function/n (dump)

If a dot-command accepts more than one argument, they are separated using comma characters (,). Spaces are generally ignored.

### 1.4.3.2 Commands

Regular poke commands are written in Poke and use different conventions. The name of commands follow the same rules as normal Poke identifiers, and do not start with a dot character.

An example is the `dump` command:

```
(poke) dump
76543210 0011 2233 4455 6677 8899 aabb ccdd eeff 0123456789ABCDEF
00000000: 7f45 4l46 0201 0100 0000 0000 0000 0000 ....ELF...........
00000010: 0100 f700 0100 0000 0000 0000 0000 0000 ............
00000020: 0000 0000 0000 0000 8001 0000 0000 0000 ............
00000030: 0000 0000 4000 0000 0000 4000 0800 0700 ....@.....@
00000040: 1800 0000 0000 0000 0000 0000 0000 0000 ............
00000050: 7900 0000 0000 0000 b701 0000 9a02 0000 y............
00000060: 7b10 0000 0000 0000 1800 0000 0000 0000 {............
00000070: 0000 0000 0000 0000 7900 0000 0000 0000 ........y.....
```

After the name of the command, arguments can be specified by name, like this:

```
(poke) dump :from 0#B :size 8#B
76543210 0011 2233 4455 6677 8899 aabb ccdd eeff 0123456789ABCDEF
00000000: 7f45 4c46 0201 0100 0000 0000 0000 0000 ....ELF........
00000010: 0100 f700 0100 0000 0000 0000 0000 0000 ............
00000020: 0000 0000 0000 0000 8001 0000 0000 0000 ............
00000030: 0000 0000 4000 0000 0000 4000 0800 0700 ....@.....@
00000040: 1800 0000 0000 0000 0000 0000 0000 0000 ............
00000050: 7900 0000 0000 0000 b701 0000 9a02 0000 y............
00000060: 7b10 0000 0000 0000 1800 0000 0000 0000 {............
00000070: 0000 0000 0000 0000 7900 0000 0000 0000 ........y.....
```

The `dump` command is discussed in greater detail below (see Section 24.1 [dump], page 126). The order of arguments is irrelevant in principle:

```
(poke) dump :from 0#B :size 8#B :ascii 0 :ruler 0
00000000: 7f45 4c46 0201 0100 0000 0000 0000 0000 ....ELF....
00000010: 0100 f700 0100 0000 0000 0000 0000 0000 ............
00000020: 0000 0000 0000 0000 8001 0000 0000 0000 ............
00000030: 0000 0000 4000 0000 0000 4000 0800 0700 ....@.....@
00000040: 1800 0000 0000 0000 0000 0000 0000 0000 ............
00000050: 7900 0000 0000 0000 b701 0000 9a02 0000 y............
00000060: 7b10 0000 0000 0000 1800 0000 0000 0000 {............
00000070: 0000 0000 0000 0000 7900 0000 0000 0000 ........y.....
```

However, beware side effects while computing the values you pass as the arguments! The expressions themselves are evaluated from left to right (according to the order of declaration in the signature).

Which arguments are accepted, and their kind, depend on the specific command.

Note that the idea is to restrict the number of dot-commands to the absolutely minimum. Most of the command-like functionality provided in poke shall be implemented as regular commands.
1.4.4 Command Files

Command files contain poke commands. A poke command may be a dot command, a Poke statement or a Poke expression. Lines starting with # are comments will be ignored. However a comment must start at the beginning of a line. Here is an example of a script:

```
# The following two lines are dot commands
.load my-pickle.pk
.set obase 16

# The following line is a Poke statement
dump :size 0x100#B :from 0x10#B

# The following line is a Poke expression statement without any side effect.
# Consequently it is valid, but rather useless.
4 == 4
```

A command file contains commands, not Poke code. This means it gets read line by line and commands cannot occupy more than one line. Hence the following is a valid command file:

```
type foo = struct {int this; int that;}
```

but this is not valid as a command file (although it is a valid Poke statement) and will provoke an error:

```
type foo = struct
{
  int this;
  int that;
}
```

Command files can be loaded at startup using the -s command line option (see Section 1.3 [Invoking poke], page 4). The ~/.pokerc startup file is also an example of a poke command file (see Chapter 8 [pokerc], page 97).

1.4.5 Scripts

Following the example of Guile Scheme, the Poke syntax includes support for multi-line comments using the #! and !# delimiters. This, along with the -L command line option, allows to write Poke scripts and execute them in the command line like if they were normal programs. Example of a script:

```
#!/usr/bin/poke -L
#!

print "Hello world!\n";
```

The resulting script can process command-line options by accessing the argv array. The following Poke script prints its arguments:

```
#!/usr/bin/poke -L
#!

for (arg in argv)
  printf ("Argument: %s\n", arg);
```

If you want to pass additional flags to the poke command, you need to use a slightly different kind of shebang:

```
#!/usr/bin/env sh
exec poke -L "$0" "$@"
#!
```
load elf;
open (argv[0]);
printf "%v\n", Elf64_Ehdr 0#B);
2 Setting Up

2.1 Setting up Hyperlinks

GNU poke uses *terminal hyperlinks* in order to improve the interactive usage of the tool: clicking on terminal hyperlinks requests poke to execute certain actions. This is used to implement buttons and other interactive goodies.

Many terminal emulators support terminal hyperlinks. However, we are using a very simple protocol called `app://` that is not supported (yet) on GNU/Linux distros. Fortunately, it is very easy to set your system to use this protocol, and this chapter shows you how.

2.1.1 Make sure your poke speaks hyperlinks

The first step in having an hyperlinks-capable poke is to make sure to have a recent enough version of `libtextstyle` when building poke. If your poke can emit hyperlinks you will see a message like this when running it on the terminal:

```
hserver listening in port 43713.
```

2.1.2 Use a terminal emulator that supports hyperlinks

Gnome Terminal has support for displaying hyperlinks as do many other emulators that rely on VTE. Check the list at https://gist.github.com/egmontkob/eb114294efbcd5adb1944c9f3cb5fedad#supporting-apps for a mostly up-to-date, non-exhaustive list of emulators that support printing hyperlinks.

2.1.3 Get and install the app-client utility

Since `app://` is a new URI protocol that we designed, common terminal emulators don’t know what to do when they encounter such a URI. To work around this problem we use the XDG Desktop Specification and a little C utility called `app-client`, which can be found at https://gitlab.com/darnir/hyperlink-app-client.

By setting `app-client` as the default handler for `app://` URIs, the terminal emulator does not need to understand the syntax or semantics of the `app://` protocol. It offloads the handling of the URI entirely to `app-client`. In order to use this, first download and install `app-client`:

```
$ git clone https://gitlab.com/darnir/hyperlink-app-client
$ cd hyperlink-app-client
$ make
$ sudo make install
```

This is enough for any utility (like terminals) that use `xdg-open` to do the right thing with hyperlinks. However, certain terminals require additional setup. See below if that is your case.

2.1.4 GNOME Terminal

Gnome Terminal doesn’t use `xdg-open` to start the applications. Instead, it parses the `mimeapps.list` file manually to find the right application.

Edit your `mimeapps.list`, it is usually located at `$HOME/.local/share/applications/mimeapps.list` but it might also be at `$XDG_CONFIG_DIR/mimeapps.list`, and add the following line to it:

```
x-scheme-handler/app=app-client.desktop
```

This let’s Gnome Terminal know how to open `app://` links.
2.2 Simple Init File

GNU poke is a spartan program that tries to be as simple as possible by default, without fancy displays. Therefore, before exploring poke you may want to configure it minimally. This section contains a few recommendations in that respect.

First we must say that poke reads a per-user configuration from the ~/.poker.c file. See Chapter 8 [poker.c], page 97.

We recommend new users to set the following options:

- set endian little
- set omode tree
- set oacutoff 5
- set pretty-print yes
- set pager yes

.set endian little will make poke to use little-endian by default when accessing IO spaces, such as files or memory buffers. See Section 3.7 [Big and Little Endians], page 20.

.set omode tree will make poke to format composite data structures, such as arrays and struct, in several lines in a nice tree-like format. By default the program will format these values in a single line (what we call the “plain” output mode) which can be difficult to read.

.set oacutoff 5 will make poke to output at most five elements in array values, followed by a diereisis ....

.set pretty-print yes will make poke to use pretty-printers when printing out values of struct types that have a pretty-printer defined for them. You can recognize pretty-printed values because, by convention, they are emitted between #< and > markers, like for example #<leb128:1234>. If you see a pretty-printed value and you need to look at its internal structure, you can disable pretty-printing using a .set pretty-print no dot-command at any time. See Section 6.1 [Pretty-printers], page 85.

.set pager yes will make poke to page the output of commands that emit output larger than the visible terminal. This of course only has an effect when running poke interactively.

These options are fully explained later in this manual. See Section 23.14 [set command], page 122.
3 Basic Editing

In this chapter you will learn how to shuffle binary data around with poke, in terms of fundamental predefined entities: bits, bytes, integers, and the like.

3.1 Binary Files

GNU poke is an editor for binary files. Right, so what is a binary file? Strictly speaking, every file in a computer’s file system is binary. This is because, in a very fundamental level, files are just sequences of bytes.

Colloquially, however, it is very common to talk about “binary files” as opposed to “text files”. In this informal meaning, a text file is basically a file composed, mostly, of bytes (and byte sequences) that can be translated into printable characters in some character set, such as ASCII, EBCDIC or Unicode. It follows that binary files would then be files composed, mostly, of bytes not intended to be interpreted as encoded characters.

Some text files contain non-printable characters, such as form feed characters, and many binary files contain printable strings, such as a string table in an ELF object file. That is why we used the word “mostly” in the definitions above. In practice, however, the distinction is almost always clear and there is common consensus on whether a given file format can be considered as a binary format, or not.

GNU poke can edit any file, and as we shall see, it provides some nice features to manipulate sequences of bytes interpreted as character strings. However, it is called a “binary editor” because it is especially designed to be particularly useful editing binary files, in the sense of the term defined above.

In this chapter, we will be using ELF object files as the experiment subject in most of the examples. ELF files are good for this purpose, because they are eminently binary, highly structured, and still strings play a role in them, encoding names of entities like sections and symbols. You don’t need to have a perfect knowledge of the ELF format in order to follow the examples, but being familiarized with the concept of object file formats should surely help.

You will need to install the ELF pickle. You can get it at https://jemarch.net/poke-elf.

Obtaining a simple ELF object file is easy, if you have a C compiler installed:

$ echo 'int foo () { return 0; }' | gcc -c -xc -o foo.o -

The command above compiles a very simple ELF object file that contains the compiled form of a little dummy function. This object file will be our companion for a while, and will be the subject of much analysis and abuse, as we poke it.

3.2 Files as IO Spaces

Now that we have a binary file (foo.o) it is time to open it with poke. There are two ways to do that.

One way is to pass the name of the file in the poke invocation. The program will start, open the file, and present you with the REPL, like in:

$ poke foo.o
[...]
(poke)

The other way is to fire up poke without arguments, and then use the .file dot-command to open the file:

$ poke
[...]
(poke) .file foo.o
Chapter 3: Basic Editing

The current IOS is now `.foo.o'.

(poke)

Note how poke replies to the dot-command, stating that the current IOS is now the file we opened.

You may be wondering, what is this IOS thing? It is an acronym for Input/Output Space, often written IO Space. This is the denomination used to refer to the entities being edited with poke. In this case the IO space being edited is a file, but we will see that is not always the case: poke can also edit other entities such as memory buffers and remote block-oriented devices over the network. For now, let’s keep in mind that IOS, or IO space, refers to the file being edited.

And why “current”? GNU poke is capable of editing several files (more generally, several IO spaces) simultaneously. At any time, one of these files is the “current one”. In our case, the current IO space is the file foo.o, since it is the only file poke knows about:

(poke) .info ios

<table>
<thead>
<tr>
<th>Id</th>
<th>Type</th>
<th>Mode</th>
<th>Bias</th>
<th>Size</th>
<th>Name</th>
</tr>
</thead>
<tbody>
<tr>
<td>* 0</td>
<td>FILE</td>
<td>rw</td>
<td>0x00000000#B</td>
<td>0x00000398#B</td>
<td>./foo.o</td>
</tr>
</tbody>
</table>

The command .info ios gives us information about all the IO spaces that are currently open. The first column tells us a positive integer that identifies the IOS. This IO space identifier is unique at any given time. In this example, the id corresponding to foo.o is 0. The second column tells us the type of IO space. The third column tells us that foo.o allows both reading and writing. The fourth column tells us the size of the file, in hexadecimal. The fifth column is the name of the IO space; in this case, it is the path to the file being edited.

You may wonder what is that weird suffix #B. It is a unit, and tells us that the size 0x398 is measured in bytes, i.e. the size of foo.o is 0x398 bytes (or, in decimal, 920 bytes.)

Finally, the asterisk character at the left of the entry for foo.o identifies it as the current IO space. To see this more clearly, let’s open another file:

(poke) .file bar.o

The current IOS is now `.bar.o'.

(poke) .info ios

<table>
<thead>
<tr>
<th>Id</th>
<th>Type</th>
<th>Mode</th>
<th>Bias</th>
<th>Size</th>
<th>Name</th>
</tr>
</thead>
<tbody>
<tr>
<td>* 1</td>
<td>FILE</td>
<td>rw</td>
<td>0x00000000#B</td>
<td>0x00000398#B</td>
<td>./bar.o</td>
</tr>
<tr>
<td>0</td>
<td>FILE</td>
<td>rw</td>
<td>0x00000000#B</td>
<td>0x00000398#B</td>
<td>./foo.o</td>
</tr>
</tbody>
</table>

Ah, there we have both foo.o and bar.o. Now the current IO space (the entry featuring the asterisk at the left) is the file that we just opened, bar.o. This is because poke always sets the most recently open file as the current one. We can switch back to foo.o using yet another dot-command, .ios, which gets an IO space as an argument:

(poke) .ios 0

The current IOS is now `.foo.o'.

(poke) .info ios

<table>
<thead>
<tr>
<th>Id</th>
<th>Type</th>
<th>Mode</th>
<th>Bias</th>
<th>Size</th>
<th>Name</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>FILE</td>
<td>rw</td>
<td>0x00000000#B</td>
<td>0x00000398#B</td>
<td>./bar.o</td>
</tr>
<tr>
<td>* 0</td>
<td>FILE</td>
<td>rw</td>
<td>0x00000000#B</td>
<td>0x00000398#B</td>
<td>./foo.o</td>
</tr>
</tbody>
</table>

We are back to foo.o. Since we are not really interested in bar.o, let’s close it:

(poke) .close 1

(poke) .info ios

<table>
<thead>
<tr>
<th>Id</th>
<th>Type</th>
<th>Mode</th>
<th>Bias</th>
<th>Size</th>
<th>Name</th>
</tr>
</thead>
<tbody>
<tr>
<td>* 0</td>
<td>FILE</td>
<td>rw</td>
<td>0x00000000#B</td>
<td>0x00000398#B</td>
<td>./foo.o</td>
</tr>
</tbody>
</table>

Note how in the examples above we used the IO space identifiers (0 and 1) in order to refer to them. This can be inconvenient, as these ids are not memorable at all. Fortunately it is also possible to refer to an IO space by name using the $<name> construct, like this:
Chapter 3: Basic Editing

(poke) .ios $<./foo.o>
The current IOS is now `./foo.o'.
(poke) .close $<./bar.o>

Note that the $<name> construct is lenient in the sense that it will accept any non-empty substring that identifies an existing IO space in an unambiguous way. This is useful in order to avoid having to write annoying paths. For example:

(poke) .file /bin/ls
(poke) .file /bin/cat
(poke) .ios $<ls>

The current IOS is now `/bin/ls'.

Auto completion also works. Try it!

3.3 Dumping File Contents

Data stored in modern computers, in both volatile memory and persistent files, is fundamentally a sequence of entities called bytes. The bytes can be addressed by its position in the sequence, starting with zero:

+--------+--------+--------+ ... +--------+
| byte 0 | byte 1 | byte 2 | | byte N |
+--------+--------+--------+ ... +--------+

Each byte has capacity to store a little unsigned integer in the range 0..255. Therefore, the IO spaces that we edit with poke (like the file foo.o) can be seen as a sequence of little numbers, like depicted in the figure above.

GNU poke provides a command whose purpose is to display the values of these bytes: dump¹. It is called like that because it dumps ranges of bytes to the terminal, allowing the user to inspect them.

So let’s use our first poke command! Fire up poke, open the file foo.o as explained above, and execute the dump command:

(poke) dump
76543210 0011 2233 4455 6677 8899 aabb ccdd eeff 0123456789ABCDEF
00000000: 7f45 4c46 0201 0100 0000 0000 0000 0000 .ELF............
00000010: 0100 f700 0102 0000 0000 0000 0000 0000 ................
00000020: 0102 0000 0000 0000 9801 0000 0000 0000 ................
00000030: 0000 0000 4000 0000 0000 4000 0800 0700 ..............
00000040: 2564 0a00 0000 0000 0000 0000 0000 0000 %d..............
00000050: b702 0000 0100 0000 1801 0000 0000 0000 ................
00000060: 0000 0000 0000 8510 0000 ffff ffff ..............
00000070: b700 0000 0000 0000 9500 0000 0000 0000 ..............

(poke)

What are we looking at?

The first line of the output, starting with 76543210, is a ruler. It is there to help us to visually determine the location (or offset) of the data.

The rest of the lines show the values of the bytes that are stored in the file, 16 bytes per line. The first column in these data lines shows the offset, in hexadecimal and measured in number of bytes, from which the row of data starts. For example, the offset of the first byte shown in the third data line has offset 0x20 in the file, the second byte has offset 0x21, and so on. Note how the data rows show the values of the individual bytes, in hexadecimal. Generally speaking,

¹ Note that this is not a dot-command like .file, .ios or .close: dump does not start with a dot! We will see later how dot-commands differ from “normal commands” like dump, but for now, let’s ignore the distinction.
when dealing with bytes (and binary data in general) it is useful to manipulate magnitudes in hexadecimal, or octal. This is because it is easy to group digits in these bases to little groups of bits (four and three respectively) in the equivalent binary representation. In this case, each couple of hexadecimal digits denote the value of a single byte\(^2\). For example, the value of the first byte in the third data row is 0x01, the value of the second byte 0x02, and so on.

Using the ruler and the column of offsets, locating bytes in the data is very easy. Let’s say for example we are interested in the byte at offset 0x68: we use the first column to quickly find the row starting at 0x60, and the ruler to find the column marked with 88. Cross column and row and... voila! The byte in question has the value 0x85. The reverse process is just as easy. What is the offset of the first 0x40 in the file? Try it!

The section at the right of the output is the ASCII output. It shows the row of bytes at the left interpreted as ASCII characters. Non-printable characters are shown as . to avoid scrambling the terminal, and yes, there is actually way to customize what character to use, so they are not confused from real ASCII dot characters (0x2e) :P In this particular dump we can see that near the beginning of the file there are three bytes whose value, if interpreted as ASCII characters, conform the string “ELF”. As we shall see, this is part of the ELF magic number. Again, the ruler is very useful to locate the byte corresponding to some character in the ASCII section, or the other way around. What is the value of the byte corresponding to the F in ELF? Try it!

Something to notice in the dump output above is that these are not, by any mean, the complete contents of the file foo.o. The .info ios dot-command informed us in the last section that foo.o contains 920 bytes, of which the dump command only showed us... 0x80 bytes, or 128 bytes in decimal.

dump is certainly capable of showing more (and less) than 128 bytes. We can ask dump to display some given amount of data by specifying its size using a command argument. For example:

```
(poke) dump :size 64#B

76543210 0011 2233 4455 6677 8899 aabb ccdd eeff 0123456789ABCDEF
00000000: 7f45 4c46 0201 0100 0000 0000 0000 0000 .ELF............
00000010: 0100 f700 0102 0000 0000 0000 0000 0000 ................
00000020: 0102 0000 0000 0000 9801 0000 0000 0000 ................
00000030: 0000 0000 4000 0000 0000 4000 0800 0700 ..............
```

The command above asks poke to “dump 64 bytes”. In this example :size is the name of the argument, and 64#B is the argument’s value. Again, the suffix #B tells poke we want to dump 64 bytes, not 64 kilobits nor 64 potatoes.

Another interesting aspect of our first dump (ahem) is that the dumped bytes start from the beginning of the file, i.e. the offset of the first byte is 0x0. Certainly there should be other areas of the file with interesting contents for us to inspect. To that purpose, we can use yet another option,:from:

```
(poke) dump :size 64#B :from 128#B

76543210 0011 2233 4455 6677 8899 aabb ccdd eeff 0123456789ABCDEF
00000080: 1400 0000 0000 0000 0000 0000 0000 0000 ................
00000090: 0000 0000 0000 0000 0000 0000 0000 0000 ................
000000a0: 0000 0000 0300 0100 0000 0000 0000 0000 ................
000000b0: 0000 0000 0000 0000 0000 0300 0300 ................
```

The command above asks poke to “dump 64 bytes starting at 128 bytes from the beginning of the file”. Note how the first row of bytes start at offset 0x80, i.e. 128 in decimal.

---

\(^2\) Do not be fooled by the fact dump shows the hexadecimal digits in groups of four: this is just a visual aid and, as we shall see, it is possible to change the grouping by passing arguments to dump.
Passing options to commands is easy and natural, but we may find ourselves passing the same values again and again to certain command options. For example, if the default size of `dump` of 128 bytes is not what you prefer, because you have a particularly tall monitor, or you are one of these people using sub-atomic sized fonts, it can be tiresome and error-prone to pass `:size` to `dump` every time you use it. Fortunately, the default size can be customized by setting a `global variable`:

```
(poke) pk_dump_size = 160#B
```

This tells `poke` to set 160 bytes as the new value for the `pk_dump_size` variable. This is a global variable that the `dump` command uses to determine how much data to show if the user doesn’t specify an explicit value with the `:size` option. Many other commands use the same strategy in order to alter their default behavior, not just `dump`.

And now that we are talking about that, it is also cumbersome to have to set the default size used by `dump` every time we run `poke`. But no problem, just set the variable in a file called `.pokerc` in your home directory, like this:

```
pk_dump_size = 160#B
```

Every time `poke` starts, it reads `~/.pokerc` and executes the commands contained in it. See Chapter 8 [pokerc], page 97.

The `dump` command is very flexible, and accepts a lot of options and customization variables that we won’t be covering in this chapter. For a complete description of the command, see Section 24.1 [dump], page 126.

### 3.4 Poking Bytes

Let’s look again at the first bytes of the file `foo.o`:

```
(poke) dump :size 64#B
76543210 0011 2233 4455 6677 8899 aabb ccdd eeff 0123456789ABCDEF

00000000: 7f45 4c46 0201 0100 0000 0000 0000 0000 .ELF............
00000010: 0100 f700 0102 0000 0000 0000 0000 0000 ................
00000020: 0102 0000 0000 0000 9801 0000 0000 0000 ................
00000030: 0000 0000 4000 0000 0000 4000 0800 0700 ..............
```

At this point we know how to use the ruler to localize specific bytes just by looking at the displayed data. If we wanted to operate on the values of some given bytes, we could look at the `dump` and type the values in the REPL. For example, if we wanted to add the values of the bytes at offsets 0x2 and 0x4, we could look at the `dump` and then type:

```
(poke) 0x4c + 0x02
0x4e
```

GNU `poke` supports many operators that take integers as arguments, to perform arithmetic, relational, logical and bit-wise operations on them (see Section 25.2 [Integers], page 131). Since bytes are no more (and no less) than little unsigned integers, we can use these operators to perform calculations on bytes.

For example, this is how we would calculate whether the highest bit in the second byte in `foo.o` is set:

```
(poke) 0x45 & 0x80
0
```

Note how booleans are encoded in `Poke` as integers, 0 meaning false, any other value meaning true.

Looking at the output of `dump` and writing the desired byte value in the prompt is cumbersome. Fortunately, there is a much more convenient way to access the value of a byte, given its
offset in the file: it is called *mapping* a byte value. This operation is implemented by a binary operator, called the map operator.

This is how it works. Assuming we were interested in the byte at 64 bytes from the beginning of the file, this is how we would refer to it (or “map” it):

```
(poke) byte @ 64#B
```

37UB

This application of the map operator tells poke to map a byte at the offset 64 bytes. It can be read as “byte at 64 bytes”. Note how poke replies with the value 37UB. The suffix UB means “unsigned byte”, and is an indication for the user about the nature of the preceding number: it is unsigned, and it occupies a byte when stored.

As we can see in this example, poke uses decimal by default when showing values in the REPL. We already noted how it is usually better to work in hexadecimal when dealing with byte values. Fortunately, we can change the numeration base used by poke when printing numbers, using the `.set obase` ("set output base") dot-command as this:

```
(poke) .set obase 16
After this, we can map the byte again, this time getting the result expressed in hexadecimal:
```

```
(poke) byte @ 64#B
```

0x25UB

Again, you may find it useful to add the `.set obase 16` command to your `.pokerc` file, if you want the customization to be persistent between poke invocations.

Going back to the example of calculating whether the highest bit in the second byte in `foo.o` is set, this is how we would do it with a map:

```
(poke) (byte @ 2#B) & 0x80
```

0

Turns out the answer is no.

The map operator can also be used at the left side of an assignment operator:

```
(poke) byte @ 0x28#B = 0xff
```

Which reads “assign 0xff to the byte at offset 0x4a bytes”. Dumping again, we can verify that the byte actually changed:

```
76543210 0011 2233 4455 6677 8899 aabb ccdd eeff 0123456789ABCDEF
00000000: 7f45 4c46 0201 0100 0000 0000 0000 0000 .ELF...........
00000010: 0100 f700 0102 0000 0000 0000 0000 0000 ................
00000020: 0102 0000 0000 0000 ff01 0000 0000 0000 .............
00000030: 0000 0000 4000 0000 0000 4000 0800 0700 ..............
```

Does this mean that `foo.o` changed accordingly, in disk? The answer is yes. poke always commits changes immediately to the file being edited. This, that is an useful feature, can also be a bit tricky if you forget about it, leading to data corruption, so please be careful.

Incidentally, altering the byte at offset 0x28 most probably have caused `foo.o` to stop being a valid ELF file, but since we are just editing bytes (and not ELF structures) we actually don’t care much.

### 3.5 Values and Variables

Up to now we have worked with byte values, either writing them in the REPL or mapping them at the current IO space. Often it is useful to save values under meaningful names, and access to them by name. In poke we do that by storing the values in *variables*.

Before being used, variables shall be defined using the `var` construction. Let’s get the byte at offset 64 bytes and save it in a variable called `foo`:

```
(poke) var foo = byte @ 64#B
```
This defines a new variable (foo) and initializes it to the value of the byte at offset 64 bytes. This results on foo to hold the value 37.

Once defined, we can get the value of a variable by just giving its name to poke:

```
(poke) foo
37UB
```

Several variables can be defined in a single var declaration. Each definition is separated by a comma. This is equivalent of issuing several vars:

```
(poke) var a = 10, b = 20
```

In general, a variable containing a byte value can be used in any context where the contained value would be expected. If we wanted to check the highest bit in the byte value stored in foo we would do:

```
(poke) foo & 0x80
0x0
```

Assigning a value to a variable makes the value the new contents of the variable. For example, we can increase the value of foo by one like this:

```
(poke) foo = foo + 1
```

At this point, an important question is: when we change the value of the variable foo, are we also changing the value of the byte stored in foo.o at offset 64 bytes? The answer is no. This is because when we do the mapping:

```
(poke) var foo = byte @ 64#B
```

The value stored in foo is a copy of the value returned by the map operator @. You can imagine the variable as a storage cell located somewhere in poke’s memory. After the assignment above is executed there are two copies of the byte value 0x25: one in foo.o at offset 64 bytes, and the other in the variable foo.

It follows that if we wanted to increase the byte in the file, we would need to do something like:

```
(poke) var foo = byte @ 64#B
(poke) foo = foo + 1
(poke) byte @ 64#B = foo
```

Or, more succinctly, omitting the usage of a variable:

```
(poke) byte @ 64#B = (byte @ 64#B) + 1
```

Or, even more succinctly:

```
(poke) (byte @ 64#B) += 1
```

Note how we have to use parenthesis around the map at the right hand side, because the map operator @ has less precedence than the plus operator +.

### 3.6 From Bytes to Integers

The bytes we have been working with are unsigned whole numbers (or integers) in the range 0..255. We saw how poke sees the contents of the files as a sequence of bytes, and how each byte can be addressed using an offset. Mapping bytes using the map operator @ gives us these values, which are denoted in poke with literals like 10UB or 0x0aUB.

This very limited range of values have consequences when it comes to do arithmetic with bytes. Suppose for example we wanted to calculate the average of the first three byte values stored in foo.o. We could do something like:

```
(poke) a0 = byte @ 0#B
(poke) a1 = byte @ 1#B
(poke) a2 = byte @ 2#B
```
That is obviously the wrong answer. What happened? Let’s do it step by step. First, we add the first two bytes:

(poke) a0 + a1
0xc4UB

Which is all right. 0xc4 is 0x7f plus 0x45. But, let’s add now the third byte:

(poke) a0 + a1 + a2
0x10UB

That’s no good. Adding the value of the third byte (0x4c) we overflow the range of valid values for a byte value. The calculation went banana at this point.

Another obvious problem is that we surely will want to store integers bigger than 255 in our files. Clearly we need a way to encode them somehow, and since all we have in a file are bytes, the integers will have to be composed of them.

Integers bigger than 255 can be encoded by interpreting consecutive byte values in a certain way. First, let’s consider a single byte. If we print a byte value using binary rather than decimal or hexadecimal, we will observe that eight bits are what it takes to encode the numbers between 0 and 0xff (255) using a natural binary encoding:

(poke) .set obase 2
(poke) 0UB
0b00000000UB
(poke) 0xFFUB
0b11111111UB

This is the reason why people say bytes are “composed” of eight bits, or that the width of a byte is eight bits. But this way of talking doesn’t really reflect the view that the operating system has of devices like files or memory buffers: both disk and memory controllers provide and consume bytes, i.e. little unsigned numbers in the range 0..255. At that level, bytes are indivisible. We will see later that poke provides ways to work on the “sub-byte” level, but that is just really an artifact to make our life easier: underneath, all that goes in and out are bytes.

Anyhow, if we were to “concatenate” the binary representation of two consecutive bytes, we would end with a much bigger range of possible numbers, in the range 0b00000000..0b11111111_11111111, or 0x0000..0xffff in hexadecimal. poke provides a bit-concatenation operator ::: that does exactly that:

(poke) 0x1UB
0b00000001UB
(poke) 0x1UB ::: 0x1UB
0b0000000100000001UH

Note how the suffix of the resulting number is now UH. This indicates that the number is no longer a byte value: it is too big for that. The H in this new suffix means “half”, and it is a traditional way to call an integer that is encoded using two bytes, or 16 bits.

---

3 poke allows to insert underscore characters _ anywhere in number literals. The only purpose of these characters is to improve readability, and they are totally ignored by poke, i.e. they do not alter the value of the number.
So, using our method of encoding bigger numbers concatenating bytes, what would be the “half” integer composed of two bytes at the beginning of foo.o?

```
(poke) .set obase 16
(poke) (byte @ 0#B):::(byte @ 1#B)
0x7f45UH
```

Now, let’s go back to the syntax we used to map a byte value. In the invocation of the map operator `byte @ 0#B` the operand at the left (in this case `byte`) tells the operator what kind of value to map. This is called a type specifier; `byte` is the type specifier for a single byte value, and `byte[3]` is the type specifier for a group of three byte values arranged in an array.

As it happens, `byte` is a synonym for another slightly more interesting type specifier: `uint<8>`. You can probably infer the meaning already: a byte is an unsigned integer which is 8 bits big. We can of course use this alternate specifier in a mapping operation, achieving exactly the same result than if we were using `byte`:

```
(poke) uint<8> @ 0#B
0x7fUB
```

You may be wondering: is it possible to use a similar type specifier for mapping bigger integers, like these “halves” that are composed of two bytes? Yeah, it is indeed possible:

```
(poke) uint<16> @ 0#B
0x7f45UH
```

Mapping an unsigned integer of 16-bits at the offset 0 gives us an unsigned “half” value, as expected.

You can easily build bigger and bigger numbers concatenating more and more bytes. Three bytes? sure:

```
(poke) uint<24> @ 0#B
(uint<24>) 0x7f454c
```

Note that in this case poke uses a prefix instead of a suffix to indicate that the given value is 24-bits long. This is because only a limited number of suffixes (which are more concise and more readable than the prefix form) are available, corresponding to common or typical widths.

Four bytes?

```
(poke) uint<32> @ 0#B
0x7f454c46U
```

Certain integer widths are so often used that easier-to-type synonyms for their type specifiers are provided. We already know `byte` for `uint<8>`. Similarly, `ushort` is a synonym for `uint<16>`, `uint` is a synonym for `uint<32>` and `ulong` is a synonym for `uint<64>`. Try them!

GNU poke supports integers up to eight bytes, i.e. up to 64-bits. This may change in the future, as we are planning to support arbitrarily large integers.

### 3.7 Big and Little Endians

When talking about whole numbers (integers) we should distinguish between their value (such as 123) and their written form that we would use when writing the number on a piece of paper, such as 123.

The written form of a number is composed of digits, arranged in certain order. We all know that the ordering of the digits in the written form of a number is important: if we write 123 we are referring to a different value than if we write 321. The mathematical reason for this is that depending on the position they occupy in the written form, each digit contributes with a different “weight” to the total value of the number. This is always the case, regardless of the numerical base used to denote the number.
For example, the value of the number 123 (whose written form is 123) is calculated as $1 \times 10^2 + 2 \times 10^1 + 3 \times 10^0$. If we swap the last two digits in the written form of the number, 132, we have $1 \times 10^2 + 3 \times 10^1 + 2 \times 10^0$, which results in a different value: 132. When we consider other numerical bases, the bases in the polynomial change accordingly, but the correspondence between written form and value stands: for example, the value of 0x123 is calculated as $1 \times 16^2 + 2 \times 16^1 + 3 \times 16^0$.

The “higher” a digit is in the polynomial, the more significant it is, i.e. the more weight it has on the value of the number where it appears. In the written number 123, for example, the digit 1 is the most significant digit of the number, and the digit 3 is the least significant digit.

This distinction between the written form of a number and its value is very important. Just like in certain languages letters are read right-to-left (Arabic) or even down-to-up (Japanese) we could certainly conceive a language in which the digits of numbers were arranged from right-to-left instead of left-to-right. In such a language the written representation of 123 would be 321, not 123. In other words: the least significant digit would come first, not last, in the written form of the number.

Now when it comes to store numbers in computers, rather than writing them on a paper, the role of the paper is played by the computer’s memory, be it ephemeral (like RAM) or persistent (like a spinning hard disk or a Flash memory), which is organized as a sequence of bytes. Since we are composing numbers with bytes, it makes sense to have each byte to play the role of a digit in the written form of the bigger number. Since bytes can have values from 0 to 255, the base is 256. But what is the “written form” for our byte-composed numbers?

In the last section we tried to compose bigger integers by concatenating bytes together and interpreting the result. In doing so, we assumed (quite naturally) that in the written form of the resulting integer the bytes are ordered in the same order than they appear in the file, i.e. we assume that the written form of the number $b_1 \times 256^2 + b_2 \times 256^1 + b_3 \times 256^0$ would be $b_1 b_2 b_3$, where $b_1$, $b_2$ and $b_3$ are bytes. In other words, given a written form $b_1 b_2 b_3$, $b_1$ would be the most significant byte (digit) and $b_3$ would be the least significant byte (digit). In our world of IO spaces, the “written form” is the disposition of the bytes in the IO space (file, memory buffer, etc) being edited.

That interpretation of the written form is exactly what the bit-concatenation operator implements:

```
(poke) dump :from 0#B :size 3#B
76543210 0011 2233 4455 6677 8899 aabb cccddee e0123456789abcdef
00000000: 7f45 .EL

(poke) var b1 = byte @ 0#B
(poke) var b2 = byte @ 1#B
(poke) var b3 = byte @ 2#B
(poke) b1:::b2:::b3
(uint<24>) 0x7f454c
```

However, much like in certain human languages the written form is read from right to left, some computers also read numbers from right to left in their “written form”. Actually, turns out that most modern computers do it like that. This means that, in these computers, given the written form $b_1 b_2 b_3$ (i.e. given a file where $b_1$ comes first, followed by $b_2$ and then $b_3$) the most significant byte is $b_3$ and the least significant byte is $b_1$. Therefore, the value of the number would be $b_3 \times 256^2 + b_2 \times 256^1 + b_3 \times 256^0$.

So, given the written form of a bigger number $b_1 b_2 b_3$ (i.e. some ordering of bytes implied by the file they are stored in) there are at least two ways to interpret them to calculate the value of the number. When the written form is read from left to right, we talk about a big endian interpretation. When the written form is read from right to left, we talk about a little endian interpretation.
Given the first three bytes in `foo.o`, we can determine the value of the integer composed of these three bytes in both interpretations:

- **(poke) b1:::b2:::b3**
  - `(uint<24>) 0x7f454c`
- **(poke) b3:::b2:::b1**
  - `(uint<24>) 0x4c457f`

Remember how the type specifier `byte` is just a synonym of `uint<8>`, and how we can use type specifiers like `uint<24>` and `uint<32>` to map bigger integers? When we do that, like in:

- **(poke) `uint<24>` @ 0#B**
  - `(uint<24>) 0x7f454c`

Poke should somehow decide what kind of interpretation to use, *i.e.* how to read the “written form” of the number. As you can see from the example, poke uses the left-to-right interpretation, or big-endian, by default. But you can change it using a new dot-command: `.set endian`:

- **(poke) `.set endian little**
- **(poke) `uint<24>` @ 0#B**
  - `(uint<24>) 0x4c457f`

The currently used interpretation (also called *endianness*) is shown if you invoke the dot-command without an argument⁴:

- **(poke) `.set endian little**

Different systems use different endianness. Into a given system, it is to be expected that most files will be encoded following the same conventions. Thereforepoke provides you a way to set the endianness to whatever endianness is in the system. You do it this way:

- **(poke) `.set endian host**

### 3.8 Negative Integers

#### 3.8.1 Negative Encodings

Up to this point we have worked with unsigned integers, *i.e.* whole numbers which are zero or bigger than zero. Much like it happened with endianness, the interpretation of the value of several bytes as a negative number depends on the specific interpretation.

In computing there are two main ways to interpret the values of a group of bytes as a negative number: *one’s complement* and *two’s complement*.

At the moment GNU poke supports the two complement interpretation, which is really ubiquitous and is the negative encoding used by the vast majority of modern computers and operating systems.

We may consider adding support for one’s complement in the future, but only if there are real needs that would justify the effort (which wouldn’t be a small one ;)).

#### 3.8.2 Signed Integers

Unsigned values are never negative. For example:

- **(poke) `0UB - 1UB`**
  - `0xffUB`

Instead of getting a -1, we get the result of an unsigned underflow, which is the biggest possible value for an unsigned integer of size 8 bits: `0xff`.

---

⁴ This also applies to the other `.set` commands
When using type specifiers like uint<8> or uint<16> in a map, we get unsigned values such as 0UB. We need other type specifiers to map signed values. These look like int<8> and int<16>.

For example, let's map a signed 16-bit value from foo.o:

```
(poke) .set obase 10
(poke) int<16> @ 0#B
28515H
```

Note how the suffix of the value is now H and not UH. This means that the value is signed! But in this case the mapped integer is still positive, so let's try to get an actual negative value:

```
(poke) var h = int<16> @ 0#B
(poke) h - h - 1H
-1H
```

### 3.8.3 Mixing Signed and Unsigned Integers

Adding two signed integers gives you a signed integer:

```
(poke) 1 + 2
3
```

Likewise, adding two unsigned integers results in an unsigned integer:

```
(poke) 1U + 2U
3U
```

But, what happens if we mix signed and unsigned values in an expression? Is the result signed, or unsigned? Let's find out:

```
(poke) 1U + 2
3U
```

Looks like combining an unsigned value with a signed value gives us an unsigned value. This actually applies to all the operators that work on integer values: multiplication, division, exponentiation, etc.

What actually happens is that the signed operand is converted to an unsigned value before executing the expression. You can also convert signed values into unsigned values (and vice-versa) using cast constructions:

```
(poke) 2 as uint<32>
2U
```

Therefore, the expression 1U + 2 is equivalent to 1U + 2 as uint<32>:

```
(poke) 1U + 2 as uint<32>
3U
```

You may be wondering: why not doing it the other way around? Why not converting the unsigned operand into a signed value and then operate? The reason is that, given an integer of some particular size, the positive range that you can store in it is bigger when interpreted as an unsigned integer than when interpreted as a signed integer. Therefore, converting signed into unsigned before operating reduces the risk of positive overflow, which by the way is not allowed in poke. This of course assumes that we, as users, will be working with positive numbers more often than with negative numbers, but that is a reasonable assumption to do, as it is often the case!

### 3.9 Weird Integers

Up to this point we have been playing with integers that are built using a whole number of bytes. However, we have seen that the type specifier for an integer has the form int<N> or uint<N> for signed and unsigned variants, where N is the width of the integer, in bits. We have
used bit-sizes that are multiple of 8, which is the size of a byte. So, why is this so? Why is \( \mathbb{N} \) not measured in bytes instead?

The reason is that poke is not limited to integers composed of a whole number of bytes. You can actually have integers composed of any number of bits, between 1 and 64. So yes, \texttt{int<3>} is a type specifier for signed 3-bit integers, and \texttt{uint<17>} is a type specifier for unsigned 17-bit integers.

We call integers like this weird integers.

The vast majority of programming languages do not provide any support for weird integers. In the few cases they do, it is often in a very limited and specific way, like bitmap fields in C structs. Such constructions are often vague, obscure, and often their semantics depend on the specific implementation of the language, and/or the characteristics of the system where you run your program.

In poke, on the contrary, weird numbers are first class citizens, and they don’t differ in any way from “normal” integers which are composed of a whole number of bytes. Their interpretation is also well defined, and they keep the same semantics regardless of the characteristics of the computer on which poke is running.

3.9.1 Incomplete Bytes

Let’s consider first weird numbers that span for more than one byte. For example, an unsigned integer of 12 bits. Let’s visualize the written form of this number, i.e. the sequence of its constituent bytes as they appear in the underlying IO space:

```
| byte 0 | byte 1 |
+---------+--------+
| ::::: | ::::: |
+---------+--------+
| uint<12> |
```

All right, the first byte is used in its entirety, but only half of the second byte is used to conform the value of the number. The other half of the second byte has no influence of the value of the 12 bits number.

Now, we talk about the “second half of the byte”, but what do that means exactly? We know that bytes in memory and files (bytes in IO spaces) are indivisible at the system level: bytes are read and written one at a time, as little integers in the range \( 0..255 \). However, we can create the useful fiction that each byte is composed by bits, which are the digits in the binary representation of the byte value.

So, we can look at a byte as composed of a group of eight bits, like this:

```
+-------------------------+
| b7 b6 b5 b4 b3 b2 b1 b0 |
+-------------------------+
```

Note how we decided to number the bits in descending order from left to right. This is because these bits correspond to the base of the polynomial equivalent to the binary value of the byte, i.e. the value of the byte is \( b7*2^7+b6*2^6+b5*2^5+b4*2^4+b3*2^3+b2*2^2+b1*2^1+b0*2^0 \). In other words: at the bit level poke always uses a big endian interpretation, and the bit that “comes first” in this imaginary stream of bits is the most significant bit in the binary representation of the number. Please note that this is just a convention imposed by the poke authors: the opposite could have been chosen, but it would have been a bit confusing, as we would have to picture binary numbers in reverse order!

With this new way of looking at bytes, we can now visualize what we mean exactly with the “first half” and “second half” of the trailing byte, in our 12 bits unsigned number:

```
| byte 0 | byte 1 |
+---------+--------+
| ::::: | ::::: |
+---------+--------+
| ::::: | ::::: |
+---------+--------+
| ::::: | ::::: |
+---------+--------+
| ::::: | ::::: |
+---------+--------+
| ::::: | ::::: |
+---------+--------+
| uint<12> |
```

Thus the first half of byte 1 is the sequence of bits b7 b6 b5 b4. The second half, which is not pictured since it doesn’t contribute to the value of the number, would be b3 b2 b1 b0.

So what would be the value of the 12-bit integer? Exactly like with non-weird numbers, this depends on the current selected endianness, which determines the ordering of bytes.

If the current endianness is big, then byte 0 provides the most significant bits of the result number, and the used portion of byte 1 provides the least significant bits of the result number:

0b a7 a6 a5 a4 a3 a2 a1 a0 b7 b6 b5 b4

However, if the current selected endianness is little, then the used portion of byte 1 provides the most significant bits of the result number, and byte 0 provides the least significant bits of the result number:

0b b7 b6 b5 b4 a7 a6 a5 a4 a3 a2 a1 a0

Let’s see this in action. Let’s take a look to the value of the first two bytes in foo.o, in binary:

 binary:

```
(poke) .set obase 2
(poke) byte @ 0#B
0b01111111UB
(poke) byte @ 1#B
0b01000101UB
```

Looking at these bytes as sequences of bits, we have:

```
| byte @ 0#B | byte @ 1#B |
+---------------------------------+---------------------------------+
| 0 1 1 1 1 1 1 1 0 1 0 0 | 0 1 0 1 |
```

Let’s map our weird number at offset 0 bytes, using big endian:

```
(poke) .set endian big
(poke) uint<12> @ 0#B
(uint<12>) 0b011111110100
```

That matches what we explained before: the most significant bits of the unsigned 12 bits number come from the byte at offset 0, i.e. 01111111, whereas the least significant bits come from the byte at offset 1, i.e. 0100.

Now let’s map it using little endian:

```
(poke) uint<12> @ 0#B
(uint<12>) 0b010001111111
```

This time the most significant bits of the unsigned 12 bits number come from the byte at offset 1, i.e. 0100, whereas the least significant bits come from the byte at offset 0, i.e. 01111111.

An important thing to note is that non-weird numbers, i.e. numbers built with a whole number of bytes, are basically a particular case of weird numbers where the last byte in the written form (in the IO space) provides all its bits. The rules are exactly the same in all cases, which makes it easy to obtain predictable and natural results when building integers using poke.
3.9.2 Quantum Bytenics

The second kind of weird numbers are integers using less than 8 bits. These “sub-byte” numbers
do not use all the bits of their containing byte. Consider for example the written form of an
unsigned integer of size 5 bits:

\[
\begin{array}{c}
\text{byte} \\
\begin{array}{c}
\vdots \\
\vdots \\
\vdots \\
\vdots \\
\vdots
\end{array}
\end{array}
\]

\[
\begin{array}{c}
\text{uint}<5>
\end{array}
\]

Now let’s view the byte as a sequence of bits:

\[
\begin{array}{c}
\vdots \\
\vdots \\
\vdots \\
\vdots \\
\vdots
\end{array}
\]

\[
\begin{array}{c}
\text{uint}<5>
\end{array}
\]

What is the value of this number? Applying the general rules for building integers from bytes,
we can easily see that regardless of the current endianness the value, in binary, is:

\[
0b \ b7 \ b6 \ b5 \ b4 \ b3
\]

Let’s see this in poke:

(poke) .set obase 2
(poke) .set endian big
(poke) byte @ 0#B
0b01111111UB
(poke) uint<5> @ 0#B
(uint<5>) 0b01111
(poke) .set endian little
(poke) uint<5> @ 0#B
(uint<5>) 0b01111

3.9.3 Signed Weird Numbers

In the section discussing negative integers, we saw how the difference between a signed number
and an unsigned number is basically a different interpretation of the most significant bit. Exactly
the same applies to weird numbers.

Let’s summon our unsigned 12-bit integer at the beginning of the file foo.o:

(poke) .set endian big
(poke) uint<12> @ 0#B
(uint<12>) 0b0111111110100

The most significant bit of the resulting value (not of its written form) indicates that this number
would be positive if we were mapping the corresponding signed value. Let’s see:

(poke) int<12> @ 0#B
(int<12>) 0b01000111111
(poke) .set obase 10
(poke) int<12> @ 0#B
(int<12>) 1151

Let’s make it a bit more interesting, and change the value of the first byte in the file so we
get a negative number:

(poke) .set obase 2
(poke) byte @ 0#B = 0b1111_1111
(poke) int<12> @ 0#B
(int<12>) 0b111111110100
(poke) .set obase 10
(poke) int<12> @ 0#B
(int<12>) -12

Now, let’s switch to little endian:

(poke) .set endian little
(poke) .set obase 2
(poke) int<12> @ 0#B
(int<12>) 0b01001111111
(poke) .set obase 10
(poke) int<12> 0#B
(int<12>) 1279

### 3.10 Unaligned Integers

We have mentioned above that the data stored in computers, that we edit with poke, is arranged as a sequence of bytes. The entities we edit with poke (that we call **IO devices**) are presented to us as IO spaces. Up to now, we have accessed this IO space in terms of bytes, in commands like `dump :from 32#B` and in expressions like `2UB + byte @ 0#B`. We said that mapped integers are built from bytes read from the IO space.

However, the IO space that poke offers to us is actually a space of bits, not a space of bytes, and the poke values are mapped on this space of bits. The following figure shows this:

```
<table>
<thead>
<tr>
<th>poke values</th>
<th>uint&lt;16&gt; @ 2#b</th>
</tr>
</thead>
<tbody>
<tr>
<td>IO space</td>
<td>b</td>
</tr>
<tr>
<td>IO device</td>
<td>byte0</td>
</tr>
</tbody>
</table>
```

The main consequence of this, that you can see in the figure above, is that we can use offsets in mapping operations that are not **aligned to bytes**. You can specify an offset in bits, instead of bytes, using the `#b` suffix instead of `#B`. Little `b` means bits, and big `B` means bytes.

Let’s map an unaligned 16 bit unsigned integer in foo.o:

```
(poke) dump :from 0#B :size 3#B
76543210 0011 2233 4455 6677 8899 aabb cccd eeff 0123456789ABCDEF
00000000: 7f45 .EL
(poke) .set obase 2
(poke) byte @ 0#B
0b011111111UB
(poke) byte @ 1#B
0b01000101UB
(poke) byte @ 2#B
0b01001100UB
(poke) .set endian big
(poke) uint<16> @ 2#b
0b11111110100010101UH
```

Graphically:

```
<table>
<thead>
<tr>
<th>poke values</th>
<th>uint&lt;16&gt; @ 2#b</th>
</tr>
</thead>
<tbody>
<tr>
<td>IO space</td>
<td>b</td>
</tr>
</tbody>
</table>
```
These three levels of abstractions make it very easy and natural to work with unaligned data. Imagine for example that you are poking packages in a network protocol that is bit-oriented. This means that the packages will generally not be aligned to byte boundaries, but still the payload stored in the packages contains integers of several sizes. Other conventional binary editors or programming languages, that are almost always byte oriented, would require us to “unpack” the network data to a different, byte oriented, representation before messing with it. poke, on the contrary, allows you to directly map these integers as if they were aligned to byte boundaries, and work with them.

However, when one tries to determine the correspondence between a given poke value and the underlying bytes in the IO device, things can get complicated. This is particularly true when we map what we called “weird numbers”, i.e. numbers with partial bytes. As we saw, the rules to build these numbers were expressed in terms of bytes.

In order to ease the visualization of the process used to build integer values (especially if they are weird numbers, i.e. integers with partial bytes) one can imagine an additional layer of “virtual bytes” above the space of bits provided by the IO space. Graphically:

```
<table>
<thead>
<tr>
<th>Virtual bytes</th>
<th>virt. byte1</th>
<th>virt. byte2</th>
</tr>
</thead>
<tbody>
<tr>
<td>IO space</td>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>IO device</td>
<td>0x7f</td>
<td>0x45</td>
</tr>
</tbody>
</table>
```

It is very important to understand that the IO space is an abstraction provided by poke. The underlying file, or memory buffer, or whatever, is actually a sequence of bytes; poke translates the operations on integers, bits, bytes, etc into the corresponding byte operations, and this translation is far from trivial. Fortunately, we can let poke do the dirty job for us, and abstract ourselves from that complexity.

### 3.11 Integers of Different Sizes

When integer values of different sizes are passed to an arithmetic or relational operator, the “smaller” operand gets converted into the size of the “bigger” operand. For example:

```
(poke) 1H + 2
3
```

The operands are of size 16-bit and 32-bit respectively, and the result is a 32-bit integer. This is equivalent to:

```
(poke) 1H as int<32> + 2
3
```

### 3.12 Offsets and Sizes

Early in the design of what is becoming GNU poke I was struck by a problem that, to my surprise, would prove not easy to fix in a satisfactory way: would I make a byte-oriented program, or a bit-oriented program? Considering that the program in question was nothing less than an editor for binary data, this was no petty dilemma.

Since the very beginning I had a pretty clear idea of what I wanted to achieve: a binary editor that would be capable of editing user defined data structures, besides mere bytes and bits. I also knew I needed some sort of domain specific language to describe these structures and operate on them. How that language would look like, and what kind of abstractions it would provide, however, was not clear to me. Not at all.
So once I sketched an initial language design, barely something very similar to C structs, I was determined to not continue with the poke implementation until I had described as many as binary formats in my language as possible. That, I reckoned, was the only way to make sure the implemented language would be expressive, complete and useful enough to fulfil my requirements.

The first formats I implemented using my immature little language included ELF, FLV, MP3, BSON... all of them describing structures based on whole bytes. Even when they try to be compact, it is always by packing bit-fields in elements that are, invariably, sized as a multiple of bytes. Consequently, the language I was evolving became byte oriented as well. No doubt also influenced by my C inheritance, I would think of bit-fields either as a sort of second class citizen, or as mere results of shifting and masking.

This worked well. The language evolved to be able to express many different aspects of these formats in a very nice way, like variable-length data and holes in structures.

Consider the following definition, which is not valid in today’s Poke:

```pierce
type Data =
  struct
  {
    byte magic;
    byte count;
    byte dstart;

    byte[count] data @ dstart;
  };
```

The data starts with a byte that is a magic number. Then the size of the data stored, in bytes, and then the data itself. This data, however, doesn’t start right after `dstart`: it starts at `dstart`, which is expressed as an offset, in bytes, since the beginning of the Data. I conceived struct field labels to be any expression evaluating to an integer, which would be interpreted as a number of bytes, obviously.

Then, one day, it was the turn for IETF RFC1951, which is the specification of the DEFLATE algorithm and associated file format. Oh dear. Near the beginning of the spec document it can be read:

This document does not address the issue of the order in which bits of a byte are transmitted on a bit-sequential medium, since the final data format described here is byte- rather than bit-oriented. However, we describe the compressed block format in below, as a sequence of data elements of various bit lengths, not a sequence of bytes.

Then it goes on describing rules to pack the DEFLATE elements into bytes. I was appalled, and certainly sort of deflated as well. The purpose of my program was precisely to edit binary in terms of the data elements described by a format. And in this case, these data elements came in all sort of bit lengths and alignments. This can be seen in the following RFC1951 excerpt, that describes the header of a compressed block:

Each block of compressed data begins with 3 header bits containing the following data:

```
first bit    BFINAL
next 2 bits  BTYPE
```

Note that the header bits do not necessarily begin on a byte boundary, since a block does not necessarily occupy an integral number of bytes.

At this point I understood that my little language on the works would never be capable to describe the DEFLATE structures naturally: C-like bit-fields, masking and shifting, all based
on byte-oriented containers and boundaries, would never provide the slickness I wanted for my editor. I mean, just use C and get done with it.

This pissed me off. Undoubtedly other formats and protocols would be impacted in a similar way. Even when most formats are byte oriented, what am I supposed to tell to the people hacking bit-oriented stuff? “Sorry pal, this is not supported, this program is not for you”? No way, I thought, not on my watch.

The obvious solution for the problem, is to be general. In this case, to express every offset and every memory size in bits instead of bytes. While this obviously gives the language maximum expressiveness power, and is ideal for expressing the few bit-oriented formats, it has the disadvantage of being very inconvenient for most situations.

To see how annoying this is, let’s revisit the little BitData structure we saw above. In a bit-oriented description language, we would need to write something like:

```c
typedef BitData =
struct
{
    byte magic;
    byte count;
    byte dstart;

    byte[count] data @ dstart * 8;
};
```

Yeah... exactly. The * and 8 keys in the keyboards of the poke users would wear out very fast, not to mention their patience as well. Also, should I provide both sizeof and bitsizeof operators? Nasty.

I am very fond of the maxim “Never write a program you would never use yourself”\(^5\), so I resigned myself to make GNU poke byte oriented, and to provide as many facilities for operating on bit-fields as possible.

Fortunately, I have smart friends... During one of the Rabbit Herd’s Hacking Weekends\(^6\) I shared my frustration and struggle with the other rabbits, and we came to realize that offsets and data sizes in Poke should not be pure magnitudes or mere integer values: they should be united. They should have units.

It makes full sense when you come to think about it. For a program like poke, it is only natural to talk about different memory units, like bits, bytes, kilobytes, megabits, and so on. Bits and bytes are just two common units.

The syntax that we eventually used to denote united values is to specify the magnitude part, a hash (`#`) character, and then the unit. For example, the size “three bytes” is expressed as 3B, and “three bits” as 3b.

Apart from allowing me to express values in different units, this approach also has other benefits as we will see shortly.

I’m really grateful to Bruno Haible, Luca Saiu and Nacho Gonzalez for putting me on the right track.

### 3.13 Buffers as IO Spaces

We have mentioned already that files are not the only entities that can be edited using poke. Remember the dot-command `.file` that opened a file as an IO space?

```
(poke) .file foo.o
```

---

5. Actually it is Lord Vetinari’s “Never build a dungeon you can’t get out of.” but the point is the same.

6. [http://www.jemarch.net/rhw](http://www.jemarch.net/rhw)
The current IOS is now `./foo.o'.

```
(poke) .info ios
   Id  Type  Mode  Bias  Size      Name
*  0  FILE   rw   0x00000000#B  0x000004c8#B  ./foo.o
```

Memory buffers can be created using a similar dot-command, `.mem:

```
(poke) .mem foo
The current IOS is now `*foo*'.
(poke) .info ios
   Id  Type   Mode   Bias  Size      Name
*  1  MEMORY  0x00000000#B  0x00001000#B  *foo*
   0  FILE   rw   0x00000000#B  0x000004c8#B  ./foo.o
```

Note how the name of the buffer is built by prepending and appending asterisks. Therefore, the name of the buffer created by the command `.mem foo` is `*foo*`. Note also that the new buffer is created with a default size of 0x1000 bytes, or 4096 bytes. The contents of the buffer are zeroed:

```
(poke) dump
76543210  0011  2233  4455  6677  8899  aabb  ccdd  eeff  0123456789ABCDEF
00000000:  0000  0000  0000  0000  0000  0000  0000  0000  ................
00000010:  0000  0000  0000  0000  0000  0000  0000  0000  ................
00000020:  0000  0000  0000  0000  0000  0000  0000  0000  ................
00000030:  0000  0000  0000  0000  0000  0000  0000  0000  ................
00000040:  0000  0000  0000  0000  0000  0000  0000  0000  ................
00000050:  0000  0000  0000  0000  0000  0000  0000  0000  ................
00000060:  0000  0000  0000  0000  0000  0000  0000  0000  ................
00000070:  0000  0000  0000  0000  0000  0000  0000  0000  ................
```

Memory buffer IO spaces grow automatically when a value is mapped beyond their current size. This is very useful when populating newly created buffers. However, for security reasons, there is a limit: the IO spaces are only allow to grow 4096 bytes at a time.

When it comes to map values, there is absolutely no difference between an IO space backed by a file and an IO space backed by a memory buffer. Exactly the same rules apply in both cases.

### 3.14 Copying Bytes

Memory buffer IO spaces are cheap, and they are often used as “scratch” areas.

Suppose for example we want to experiment with the ELF header of `foo.o`. We could open it in poke:

```
(poke) .file foo.o
The current IOS is now `./foo.o'.
```

The header of an ELF file comprises the first 64 bytes in the file:

```
(poke) dump :size 64#B
76543210  0011  2233  4455  6677  8899  aabb  ccdd  eeff  0123456789ABCDEF
00000000:  7f45  4c46  0201  0100  0000  0000  0000  0000  .ELF............
00000010:  0100  3e00  0100  0000  0000  0000  0000  0000  ..........>
00000020:  0000  0000  0000  0000  0000  0000  0802  0000  0000  0000  ............
00000030:  0000  0000  4000  0000  0000  0400  0b60  0a00  ................
```

We know that as soon as we poke something on an IO space, the underlying file is immediately modified. So if we start playing with `foo.o`'s header, we may corrupt the file. We could of course
make a copy of `foo.o` and work on the copy, but it is much better to create a memory IO space
and copy the ELF header there:

```
(poke) .mem scratch
The current IOS is now `*scratch*'.
(poke) copy :from_ios 0 :from 0#B :size 64#B
(poke) dump :size 64#B
76543210 0011 2233 4455 6677 8899 aabb ccdd eeff 0123456789ABCDEF
00000000: 7f45 4c46 0201 0100 0000 0000 0000 0000 .ELF............
00000010: 0100 3e00 0100 0000 0000 0000 0000 0000 ..>............
00000020: 0000 0000 0000 0000 0802 0000 0000 0000 0000 ............
00000030: 0000 0000 4000 0000 0000 4000 0b00 0a00 ................
```

The command `copy` above copies 64 bytes starting at byte 0 from the IO with id 0 (the file
`foo.o`) to the current IO space (the buffer `*scratch*').

Once we are done working with the copy of the ELF header, and satisfied, we can copy it
back to the file and close the memory IO space:

```
(poke) copy :from 0#B :size 64#B :to_ios 0
(poke) .close
The current IOS is now `./foo.o'.
```

Note how the command arguments :from_ios and :to_ios are assumed to be the current IO
space if they are not explicitly specified in the command invocation. For detailed information
on the `copy` command, see Section 24.2 [copy], page 128.

### 3.15 Saving Buffers in Files

Another useful command when working with buffer IO spaces (and in general, with any IO
space) is `save`. Let's say we want to save a copy of the header of an ELF file in another file. We
could do it the pokeish way:

```
$ poke foo.o
[...]
(poke) save :from 0#B :size 64#B :file "header.dat"
```

The command above saves the first 64 bytes in the current IO space (which is backed by the file
`foo.o`) into a new file `header.dat` in the current working directory.

Let's now consider again the scenario where we are using a memory IO space as a scratch
area. It is late in the night and we are tired, so we would like to save the contents of the scratch
buffer to a file, so we can continue our work tomorrow. This is how we would do that:

```
(poke) .info ios
  Id Type Mode Bias Size Name
* 1 MEMORY 0x00000000#B 0x00001000#B  *scratch*  
0 FILE rw 0x00000000#B 0x000f4241#B  ./foo.o
(poke) save :from 0#B :size iosize (1) :file "scratch.dat"
```

Here we used the built-in function `iosize`, that given an IO space identifier returns its size.

### 3.16 Character Sets

Computers understand text as a sequence of codes, which are numbers identifying some partic-
ular character. A character can represent things like letters, digits, ideograms, word separators,
religious symbols, etc. Collections of character codes are called character sets.

Some character sets try to cover one or a few similar written languages. This is the case of
ASCII and ISO Latin-1, for example. These character sets are small, i.e. just a few hundred
codes.
Other character sets are much more ambitious. This is the case of Unicode, that tries to cover
the entire totality of human languages in the globe, including the fictitious ones, like klingon.
Unicode is a really big character set.

In order to store character codes in a computer’s memory, or a file, we need to encode each
character code in one or more bytes. The number of bytes needed to encode a given character
code depends on the range of codes in the containing set.

ASCII, for example, defines 128 character codes: a single byte is enough to encode every
possible ASCII character. It is very easy to encode ASCII.

Unicode, on the contrary, defines many thousand of character codes, and has room for many
more: we would need 31 bits in order to encode any conceivable Unicode character code. How-
ever, it would be wasteful to use that many bits per character: most used character codes tend
to be in lower regions of the code space. For example, the code corresponding to the Latin
letter 'a' is a fairly small number, whereas the codes corresponding to the Klingon alphabet
are really big numbers. Consequently, some systems opt to just encode a subset of Unicode, like
the first 16 bits of the Unicode space, which is called the Basic Multilingual Plane, and contains
all the characters that most people will ever need. There are also variable-length encodings of
Unicode, that try to use as less bytes as possible to encode any given code. A particularly clever
encoding of Unicode, designed by Rob Pike, is backwards compatible with the ASCII encoding,
\emph{i.e.} it encodes all the ASCII codes in one byte each, and the values of these byte are the same
than in ASCII. This clever encoding is called UTF-8.

3.17 From Bytes to Characters

3.17.1 Character Literals
poke has built-in support for ASCII, and its simple encoding: each ASCII code is encoded using
one byte. Let’s see:

\begin{verbatim}
(poke) 'a'
0x61UB
\end{verbatim}

We presented poke with the character \texttt{a}, and it answered with its corresponding code in the
ASCII character set, which is 0x61. In fact, \texttt{'a'} and 0x61UB are just two ways to write exactly
the same byte value in poke:

\begin{verbatim}
(poke) 'a' == 0x61UB
1
(poke) 'a' + 1
0x62U
\end{verbatim}

In order to make this more explicit, poke provides yet another synonym for the type specifier
\texttt{uint<8>}: \texttt{char}.

3.17.2 Classifying Characters
When working with characters it is very useful to have some acquaintance of the ASCII character
set, which is designed in a very clever way with the goal of easing certain code calculations. See
Appendix A [Table of ASCII Codes], page 267, for a table of ASCII codes in different numeration
bases.

Consider for example the problem of determining whether a byte we map from an IO space
is a digit. Looking at the ASCII table, we observe that digits all have consecutive codes, so we
can do:

\begin{verbatim}
(poke) var b = byte @ 23#B
(poke) b >= '0' && b <= '9'
1
\end{verbatim}
Now that we know that \( b \) is a digit, how could we calculate its digit value? If we look at the ASCII table again, we will find that the character codes for digits are not only consecutive: they are also ordered in ascending order 0, 1, \ldots Therefore, we can do:

\[
\begin{align*}
\text{(poke)} \ b & \quad 0x37UB \\
\text{(poke)} \ b - '0' & \quad 7UB
\end{align*}
\]

\( b \) contains the ASCII code 0x37UB, which corresponds to the character 7, which is a digit.

How would we check whether \( b \) is a letter? Looking at the ASCII table, we find that lower-case letters are encoded consecutively, and the same applies to upper-case letters. This leads to repeat the trick again:

\[
\begin{align*}
\text{(poke)} \ (b >= 'a' && b <= 'z') || (b >= 'A' && b <= 'Z') & \quad 0
\end{align*}
\]

### 3.17.3 Non-printable Characters

Not all ASCII code are printable using the glyph that are usually supported in terminals. If you look at the table in Appendix A [Table of ASCII Codes], page 267, you will find codes for characters described as “start of text”, “vertical tab”, and so on.

These character codes, which are commonly known as non-printable characters, can be represented in poke using its octal code:

\[
\begin{align*}
\text{(poke)} \ '002' & \quad 0x2UB
\end{align*}
\]

This is of course no different than using 2UB directly, but in some contexts the “character like” notation may be desirable, to stress the fact that the byte value is used as an ASCII character.

Some of the non-printable characters also have alternative notations. This includes new-line and horizontal tab:

\[
\begin{align*}
\text{(poke)} \ 'n' & \quad 0xaUB \\
\text{(poke)} \ 't' & \quad 0x9UB
\end{align*}
\]

These \ constructions in character literals are called escape sequences. See Section 25.2.2 [Characters], page 132, for a complete list of allowed escapes in character literals.

### 3.18 ASCII Strings

#### 3.18.1 String Values

Now that we know how to manipulate ASCII codes in poke, we may wonder how can we combine them to conform words or, more generally, strings of ASCII characters.

GNU poke has support for native ASCII string values. The characters conforming the string are written between " and " characters, like in:

\[
\begin{align*}
\text{(poke)} \ "word" \\
"word"
\end{align*}
\]

Note, and this is important, that string values are as atomic as integer values: they are not really composite values. The fact that "word" contains an r at position 3 is like the fact that the value 123 contains a digit 2 at position 2.

Like in character literals, poke strings support several escape sequences that help to denote non-printed characters, such as new lines and horizontal tabs. See Section 25.4.1 [String Literals], page 139.
3.18.2 Poking Strings

Let’s start with a fresh memory buffer IOS *scratch*:

(poke) .mem scratch
The current IOS is now `*scratch*'.
(poke) dump :size 48#B
76543210 0011 2233 4455 6677 8899 aabb ccdd eeff 0123456789ABCDEF
00000000: 0000 0000 0000 0000 0000 0000 0000 0000 ...............  
00000010: 0000 0000 0000 0000 0000 0000 0000 0000 ...............  
00000020: 0000 0000 0000 0000 0000 0000 0000 0000 ...............  

If we wanted to, somehow, store the word *word* in this IO space, encoded in ASCII, we could proceed as:

(poke) char @ 0x12#B = 'w'
(poke) char @ 0x13#B = 'o'
(poke) char @ 0x14#B = 'r'
(poke) char @ 0x15#B = 'd'
(poke) dump :size 48#B
76543210 0011 2233 4455 6677 8899 aabb ccdd eeff 0123456789ABCDEF
00000000: 0000 0000 0000 0000 0000 0000 0000 0000 ...............  
00000010: 0000 776f 7264 0000 0000 0000 0000 0000 ..word.........  
00000020: 0000 0000 0000 0000 0000 0000 0000 0000 ...............  

This worked. The ASCII part of the dump output, which interprets the bytes as ASCII, clearly shows the word *word* at the offset where we poked the character values. However, we can do better: string values can be mapped themselves.

String values use the type specifier string. As any other kind of value in poke, they can be mapped from an IO space:

(poke) string @ 0x12#B = "word"

Clearly that is the string resulting from the concatenation of the character values that we poked before.

The question now is: how did poke know that the last character of the string was the d at offset 0x15#B? The fact the character code 0 (also known as the NULL character) at offset 0x16#B is non-printable, doesn’t imply it is not part of the ASCII character set. Clearly, we have to pick an ASCII code and reserve it to mark the end of strings. Like the C programming language, and countless formats and systems do, poke uses the NULL character to delimit strings.

Now consider this:

(poke) "word"'length
4UL
(poke) "word"'size
40UL#b

Using the length and size attributes, poke tells us that the length of the string "word" is 4 characters, but the size of the string value is 40 bits, or 5 bytes. Why this discrepancy? The size value attribute tells how much storage space a given value required once mapped to an IO space, and in the case of strings it should count the space occupied by the terminating NULL character.

Poking string values on the IO space is as straightforward as poking integers:

(poke) string @ 0x22#B = "WORD"
(poke) dump :size 48#B
76543210 0011 2233 4455 6677 8899 aabb ccdd eeff 0123456789ABCDEF
3.18.3 From Characters to Strings

Strings can be concatenated using the string-concatenation + operators:

```
(poke) "foo" + "bar"
"foobar"
```

The string resulting from the operation above has length 6 characters, and size 7 bytes. The terminating NULL character of "foo" is lost in the operation. This is easily seen:

```
(poke) "foo"'size + "bar"'size
0x40UL#b
(poke) ("foo" + "bar")'size
0x38UL#b
```

The string concatenation operator requires two strings. Therefore, if we wanted to append a character to a string, we would get an error:

```
(poke) "Putin" + 'a'
<stdin>:1:1: error: invalid operands in expression
"Putin" + 'a';
^~~~~~~~~~~~~
```

It is possible to transform a character value (i.e. a byte value) into a string composed of that character using a cast:

```
(poke) 'a' as string
"a"
```

Using that cast, we can now append:

```
(poke) "Putin" + 'a' as string
"Putina"
```

3.19 From Strings to Characters

Despite being atomic values, poke strings can be indexed in order to retrieve individual characters:

```
(poke) "word"[2]
0x72UB
```

Note how the indexing is zero-based, i.e. the first position in the string is referred as [0], the second position with [1], and so on.

If you specify a negative index, or an index that is too big, you will get an error:

```
(poke) "word"[-1]
<stdin>:1:8: error: index is out of bounds of string
"word"[-1];
```

```
(poke) "word"[5]
<stdin>:1:8: error: index is out of bounds of string
"word"[5];
```
3.20 Strings are not Arrays

Arrays are collections of homogeneous data organized in a sequence. We have already seen (briefly) arrays of bytes, which use the type specifier `byte[]`.

Similarly, it is possible to arrange characters (which are basically little numbers) in an array, like in:

```
(poke) ['a', 'b', 'c']
[0x61UB, 0x62UB, 0x63UB]
```

However, the array above is *not* equivalent to the string "abc". The later is a simple value, whereas an array is a composite value, and also is implicitly terminated with a NULL character, *i.e.* a 0 byte.

The Poke standard library provides a couple of utility functions to convert between string values and character arrays: `catos` and `stoca`.

`catos` gets an array of characters and returns an equivalent string. For example:

```
(poke) catos(['a', 'b', 'c'])
"abc"
```

`stoca` gets a string and an array and sets the element of the array to the characters composing the string. For example:

```
(poke) stoca("abc")
[0x61UB, 0x62UB, 0x63UB]
(poke) var a = char[3]()
(poke) stoca("abc", a)
(poke) a
[0x61UB, 0x62UB, 0x63UB]
```
4 Structuring Data

In the previous chapter we learned how to manipulate pre-defined entities like bytes, integers and strings. One of the big points of poke, however, is that it allows you to define your own data abstractions, and to operate in term of them. This is achieved by defining data structures.

4.1 The SBM Format

4.1.1 Images as Maps of Pixels

There are two main ways to store two-dimensional images in computers.

One is to explicitly store the different pixels that compose the image. In these bitmaps, the pixels are arranged sequentially and implicitly organized into lines. A header typically provides information to determine how many pixels fit in each line:

```
<--- line_width --->
| pixel | pixel | ... | pixel | pixel | ... | ...
| line 1 | line 2 |
```

Several properties have to be encoded for each pixel, depending on the sophistication of the image: for monochrome images each pixel can be just either switched on or off, so a single bit could be used to encode each pixel (this is the origin of the term “bitmap”). When color is added, a bit is no longer sufficient: the color of the pixel shall be encoded in some way, typically using a color schema such as RGB, that requires triplet of little integers to be encoded. If transparency is to be supported, the degree of transparency of the pixel shall also be encoded somehow.

The other way to store an image is to store a functional description of the “painted” parts of the image. This functional description usually contains instructions like “paint a line of thickness 1 and color red from the coordinate 10,20 to coordinate 10,40”. Once executed with certain parameters (like the desired resolution) the functional description generates a bitmap. Image formats using this approach are commonly known as vectorial formats.

When it comes to bitmaps, there are a plethora of different formats out there (bmp, jpg, png) competing in terms of capabilities such as higher color depths, better resolution, support for transparency (alpha channels), higher compression level, and the like. These capabilities greatly complicate these formats, but ultimately any bitmap can be reduced to a sequence of pixels, which can be further structured in terms of lines.

We don’t know enough poke yet to handle the complications of these real-life bitmap formats, so in subsequent sections we introduce a very simple format for bitmaps, the Stupid BitMap format, or simply SBM, that we will use for learning purposes.

But please do not feel disappointed: later in this book, when we become more proficient pokers, we will be messing with these shiny complex formats as well :)

4.1.2 SBM header

A SBM file starts with a header that contains a “magic number” composed of the three bytes ‘S’ (0x53UB), ‘B’ (0x42UB) and ‘M’ (0x4dUB). The next two bytes indicate the number of pixels per line, and the number of lines, respectively. In summary:

```
SBM header
+---------------------------------------------+
| 'S' | 'B' | 'M' | ppl | lines |
+---------------------------------------------+
byte0 byte1 byte2 byte3 byte4
```

Here ppl stands for pixels-per-line. The encoding of these fields implies that the bigger image that can be encoded in SBM has dimensions 255x255.
4.1.3 SBM data

Albeit stupid, SBM is a colorful format. It supports more than a million colors, encoding each color in what is known as RGB24. In RGB24, each color is encoded using three little integers, specifying the amount of red, green and blue that, added together, compose the color.

The name RGB24 comes from the fact that each color is encoded using three bytes, or 24 bits. Therefore, each pixel in a SBM image is encoded using three consecutive bytes:

```
| Red | Green | Blue |
+-------+-------+-------+
```

Each byte in this encoding determines the amount of the base color (red, green or blue) that compose the color. We will talk more about these components later.

4.2 Poking a SBM Image

4.2.1 P is for poke

Let’s compose our first SBM image, using poke. The image we want to encode is the very simple rendering of the letter P shown in the figure below.

```
| 0 | 1 | 2 | 3 | 4 |
+---+---+---+---+---+
0 |   | * | * |   |
1 |   | * |   | * |
2 |   | * |   | * |
3 | * | * |   |   |
4 |   | * |   |   |
5 |   | * |   |   |
6 |   | * |   |   |
```

The image has seven lines, and there are five pixels per line, i.e. the dimension of the image in pixels is 5x7. Also, the pixels denoted by asterisks are red, whereas the pixels denoted with empty spaces are white. In other words, our image uses a red foreground over a white background. The “painted” pixels are called foreground pixels, the non painted pixels are called background pixels.

4.2.2 Preparing the Canvas

The first thing we need is some suitable IO space where to encode the image. Let’s fire up poke and create a memory buffer:

```
$ poke
[...]
(poke) .mem image
The current IOS is now `*image*'.
(poke) dump
76543210 0011 2233 4455 6677 8899 aabb ccdd eeff 0123456789ABCDEF
00000000: 0000 0000 0000 0000 0000 0000 0000 0000 .................
00000010: 0000 0000 0000 0000 0000 0000 0000 0000 .................
00000020: 0000 0000 0000 0000 0000 0000 0000 0000 .................
00000030: 0000 0000 0000 0000 0000 0000 0000 0000 .................
00000040: 0000 0000 0000 0000 0000 0000 0000 0000 .................
00000050: 0000 0000 0000 0000 0000 0000 0000 0000 .................
```
Freshly created memory IO spaces are 4096 bytes long, and that's big enough for our little image. If we wanted to work with more data, remember that memory IO spaces will grow automagically when poked past their size.

### 4.2.3 Poking the Header

The first three bytes of the header of a SBM file contains the magic number that identifies the file as a SBM bitmap. We can poke these bytes very easily:

```plaintext
(poke) byte @ 0#B = 'S'
(poke) byte @ 1#B = 'B'
(poke) byte @ 2#B = 'M'
```

The next couple of bytes encode the dimensions of the bitmap, in this case 5x7:

```plaintext
(poke) byte @ 3#B = 5
(poke) byte @ 4#B = 7
```

There is something worth noting in this last mapping. Even though we were poking bytes (passing the byte type specifier to the map operators) we specified the 32-bit signed integers 5 and 7 instead of 5UB and 7UB. When poke finds a situation like this, where certain kind of integers are expected but other kind are provided, it converts the value from the provided type to the expected type. This conversion may result in truncation (think about converting, say 0xfff to an unsigned byte, whose maximum possible value is 0xff) but certainly not in the case at hands.

The final header looks like:

```plaintext
(poke) dump :size 16#B
76543210 0011 2233 4455 6677 8899 aabb ccdd eeff 0123456789ABCDEF
00000000: 5342 4d05 0700 0000 0000 0000 0000 0000 SBM............
```

### 4.2.4 Poking the Pixels

Now that we have written a SBM header, we have to encode the sequence of pixels composing the image.

Recall that every pixel is encoded using three bytes, that conform a RGB24 color. We have two kinds of pixels in our image: white pixels, and red pixels. In RGB24 white is encoded as \((255,255,255)\). Pure red is encoded as \((255,0,0)\), but to make things more interesting we will be using a nicer tomato-like red \((255,99,71)\).

Therefore, poking a white pixel at some offset \(\text{offset}\) would involve the following operations:

```plaintext
(poke) byte @ offset = 255
(poke) byte @ offset+1#B = 255
(poke) byte @ offset+2#B = 255
```

Likewise, the operations to poke a tomato pixel would look like:

```plaintext
(poke) byte @ offset = 255
(poke) byte @ offset+1#B = 99
(poke) byte @ offset+2#B = 71
```

To ease things a bit, we can define variables with the color components for both foreground and background pixels:

```plaintext
(poke) var bg1 = 255
(poke) var bg2 = 255
(poke) var bg3 = 255
(poke) var fg1 = 255
```
(poke) var fg2 = 99
(poke) var fg3 = 71

Then to poke a foreground pixel would involve doing:

(poke) byte @ offset = fg1
(poke) byte @ offset+1#B = fg2
(poke) byte @ offset+2#B = fg3

At this point, you may feel that the prospect of mapping the pixels of our image is not very appealing, considering we have $5 \times 7 = 35$ pixels in our image. We will need to poke $35 \times 3 = 105$ bytes. We may feel tempted to, somehow, use a bigger integer to “encapsulate” the bytes. Using the bit-concatenation operator, we could do something like:

(poke) var bg = 255UB:::255UB:::255UB
(poke) var fg = 255UB:::99UB:::71UB
(poke) bg
(uint<24>) 0xffffff
(poke) fg
(uint<24>) 0xff6347

This encodes each color with a 24-bit unsigned integer. When looking at the hexadecimal values of \texttt{bg} and \texttt{fg} above, note that 0xff = 255, 0x63 = 99 and 0x47 = 71. Each byte seems to be in the right position in the 24-bit containing number. Now, poking a pixel at some given offset should be as easy as issuing just one map operation, right? Let’s see, using some arbitrary offset 10#B:

(poke) uint<24> @ 10#B = fg
(poke) dump :from 10#B :size 4#B
76543210 0011 2233 4455 6677 8899 aabb ccdd eeff 0123456789ABCDEF
0000000a: 4763 ff00 Gc..

If your current endianness is little (\textit{i.e.} you are running on a x86 system or similar) you will get the dump above. The bytes are reversed, and consequently the resulting pixel has the wrong color. Our little trick didn’t work :(.

So are we doomed to poke three bytes for each pixel we want to poke in our image? No, not really. The Poke language provides a construction oriented to alleviate cases like this, where several similar elements are to be “encapsulated” in a container. These constructions are called \textit{arrays}.

Using array values, we can define the foreground and background colors like this:

(poke) var bga = [255UB, 255UB, 255UB]
(poke) var fga = [255UB, 99UB, 71UB]

All the elements on an array should be of the same kind, \textit{i.e.} of the same type. Therefore, this is not allowed:

(poke) [1,"foo"]
<stdin>:1:1: error: array initializers should be of the same type
[1,"foo"];
--------

Given an array value, it is possible to query for the number of values contained in it (called \textit{elements}) by using the `\texttt{length}` value attribute. For example:

(poke) bga\texttt{.length}
3UL

 Tells us that the array value stored in the variable \texttt{bga} has three elements.

How can we poke an array value? We know that the map operator accepts two operands: a type specifier and the value to map. The type specifier of an array of three bytes is denoted
as `byte[3]`. Therefore, we can again try to poke a foreground pixel at offset `10#B`, this time using `fga`:

```ml
(poke) byte[3] @ 10#B = fga
(poke) dump :from 10#B :size 4B
76543210 0011 2233 4455 6677 8899 aabb ccdd eeff 0123456789ABCDEF
0000000a: ff63 4700 .cG.
```

This time, the bytes were written in the right order. This is because array elements are always written using their “written” ordering, with no mind to endianness. We can also map a pixel from a given offset:

```ml
(poke) byte[3] @ 10#B
[255UB,99UB,71UB]
```

### 4.2.5 Poking Lines

At this point, we could encode the 40 pixels composing the image, by issuing the same number of pokes of `byte[3]` arrays. However, we can simplify the task even further.

Our pixels are arrays of bytes, denoted by the type specifier `byte[3]`. Similarly, we could conceive arrays of 32-bit signed integers, denoted by `int[3]`, or arrays of bits, denoted by `uint<1>[3]`. But, is it possible to have arrays of other arrays? Yes, it is:

```ml
(poke) [[1,2],[3,4]]
```

The value above is an array of two arrays of two integers each. If we wanted to map such an array, what would be the type specifier we would need to use? It would be `int[2][2]`, which should be read from right-to-left as “array of two arrays of two integers”. Let’s map one from an arbitrary offset in our IO space:

```ml
(poke) int[2][2] @ 100#B
[[0,0],[0,0]]
```

Consider again the sequence of pixels composing the image. Using the information we have in the SBM header, we can group the pixels in the sequence into “lines”. In our example image, each line contains 5 pixels. It would be natural to express each line as a sequence of pixels. The first line in our image would be:

```ml
(poke) var l0 = [bga,fga,fga,bga,bga]
(poke) l0
[[255UB,255UB,255UB],[255UB,99UB,71UB],...]
```

Let’s complete the image lines:

```ml
(poke) var 10 = [bga,fga,fga,bga,bga]
(poke) var 11 = [bga,fga,fga,bga,bga]
(poke) var 12 = [bga,fga,fga,bga,bga]
(poke) var 13 = [bga,fga,fga,bga,bga]
(poke) var 14 = 13
(poke) var 15 = 14
```

Note how we exploited the fact that the three last lines of our image are identical, to avoid to write the same array thrice. Array values can be assigned, and in general manipulated, like any other kind of value, such as integers or strings.

At this point, we could poke the pixels line-by-line. What would be the type specifier for a line? A line is an array of five arrays of 3 bytes each, so the type specifier would be `byte[3][5]`. Let’s do that:

```ml
(poke) byte[3][5] @ 5#B = 10
(poke) byte[3][5] @ 10#B = 11
(poke) byte[3][5] @ 15#B = 12
(poke) byte[3][5] @ 20#B = 13
```
(poke) byte[3][5] @ 25#B = 14
(poke) byte[3][5] @ 30#B = 15
(poke) byte[3][5] @ 35#B = 16

Not bad, we went from poking 105 bytes in the IO space to poking six lines. But we can still do better...

4.2.6 Poking Images

When we poked the lines at the end of the previous section, we had to increase the offset in every map operation. This is inconvenient.

In the same way that a sequence of bytes can be abstracted in a line, a sequence of lines can be abstracted in an image. It follows that we can look at the image data as an array of lines. But lines are themselves arrays of arrays... no matter, there is no limit on the number of arrays-of levels that you can nest.

So, let’s define our image as an array of the lines defined above:

(poke) var image_data = [l0,l1,l2,l3,l4,l5]
(poke) image_data

[[[255UB,255UB,255UB], [255UB,99UB,71UB], [255UB,99UB,71UB], ...
...
]]

What would be the type specifier for an image? It would be an array of seven arrays of five arrays of three bytes each, in other words byte[3][5][7]. Let’s poke the pixels:

(poke) byte[3][5][6] @ 5#B = image_data

This is an example of how abstraction can simplify the handling of binary data: we switched from manipulating bytes to manipulate higher abstractions such as colors, lines and images. We achieved that by structuring the data in a way that reflects these abstractions. That’s the way of the Poker.

4.2.7 Saving the Image

Now that we have completed the SBM image in our buffer *image*, it is time to save it to disk. For that, we can use the save command we are already familiar with.

We know that the SBM image starts at offset 0#B, but what is the size of its entire binary representation? The header is easy: it spans for 5 bytes. The size of the sequence of pixels can be derived from the pixels per line byte, and the number of lines byte. We know that each pixel occupies 3 bytes, so calculating...

(poke) var ppl = byte @ 3#B
(poke) var lines = byte @ 4#B
(poke) save :from 0#B :size 5#B + ppl#B * lines :file "p.sbm"

Note how we expressed “ppl bytes” as ppl#B. This is the same than expressing “10 bytes” as 10#B. We will talk more about these united values later.

There is another way of getting the size of the stream of pixels. Recall that we have the entire set of pixels, structured as lines, stored in the variable image_data. Given an array, it is possible to query for its size using the 'size attribute:

(poke) .set obase 10
(poke) [1,2,3]'size
96UL#b

The above indicates that the size of the array of the three integers 1, 2 and 3 is 96 bits. Using that attribute, we can also obtain the size of the pixels in the image:

(poke) image_data'size
720UL#b
And we can use it in the save command:

(poke) save :from 0#B :size 5#B + image_data:size :file "p.sbm"

Using either strategy, at this point a file named p.sbm should have been written in the current working directory, containing our “P is for poke” image. Keep that file around, because we will be poking it further!

### 4.3 Modifying SBM Images

#### 4.3.1 Reading a SBM File

Let’s open with poke the cute image we created in the last section, p.sbm:

```
$ poke p.sbm
[...]
(poke) dump
76543210 0011 2233 4455 6677 8899 aabb ccdd eeff 0123456789ABCDEF
00000000: 5342 4d05 07ff ffff ffff 63 47 ffff SBM......cG.cG..
00000010: ffff ffff ffff ffff 63 47 ffff ffff........cG....cG
00000020: ffff ffff ffff ffff ffff ffff ffff ...........cG.....cG
00000030: ffff ffff ffff ffff ffff ffff ffff ffff .........cG.cG.....
00000040: ffff ffff ffff ffff ffff ffff ffff ffff ...........cG....
00000050: ffff ffff ffff ffff ffff ffff ffff ffff ...........cG....
00000060: ffff ffff ffff ffff ffff ffff ffff ffff ...........cG....
```

You can see the P in the ASCII column, right? If it wasn’t for the header, it would be pictured almost straight. This is because dump shows 16 bytes per row, and our image has lines that are 15 bytes long. This is a happy coincidence: you definitely shouldn’t expect to see ASCII art in the dump output of SBM files in general! :)

Now let’s read the image’s metadata from the header: pixels per line and how many lines are contained in the image:

(poke) var ppl = byte @ 3#B
(poke) ppl
5UB
(poke) var lines = byte @ 4#B
(poke) lines
7UB

All right, our image is 7x5. Knowing that each pixel occupies three bytes, and that each line contains ppl pixels, and that we have lines lines, we can map the entire image data using an array type specifier:

(poke) var image_data = byte[3][ppl][lines] @ 5#B
(poke) image_data
[[[255UB,255UB,255UB],[255UB,99UB,71UB], ...]...]

#### 4.3.2 Painting Pixels

The “P is for poke” slogan was so successful and widely appraised that the recutils\(^1\) chaps wanted to do a similar campaign “R is for recutils”. For that purpose, they asked us for a tomato-colored SBM image with an R in it.

Our creative department got at it, and after a lot of work they came with the following design:

```
| 0 | 1 | 2 | 3 | 4 |
```

\(^1\) [http://www.gnu.org/s/recutils](http://www.gnu.org/s/recutils)
Chapter 4: Structuring Data

Observe that this design really looks like our P (so much for a creative department). The bitmap has exactly the same dimensions, and differences are just three pixels, that pass from being background pixels to foreground pixels.

Therefore, it makes sense to read our p.sbm and use it as a base, completing the missing pixels. We saw in the last section how to read a SBM image. This time, however, we will copy the image first to a memory IO space to avoid overwriting p.sbm:

```sh
$ poke p.sbm
[...]
(poke) .mem scratch
The current IOS is now `*scratch*'.
(poke) .info ios
  Id  Type  Mode  Bias  Size  Name
  *   MEMORY 0x00000000#B 0x00001000#B *scratch*
  0   FILE  rw 0x00000000#B 0x0000006e#B ./p.sbm
(poke) copy :from_ios 0 :from 0#B :to 0#B :size iosize (0)
(poke) dump
```

```
76543210 0011 2233 4455 6677 8899 aabb ccdd eeff 0123456789ABCDEF
00000000: 5342 4d05 07ff ffff ffff 6347 ffff SBM......cG....cG..
00000010: ffff ffff ffff 6347 ffff ffff ffff ffff .........cG....cG
00000020: ffff ffff ffff ff63 47ff ffff ffff ffff ......cG....cG.
00000030: ffff ffff ffff 6347 ff63 47ff ffff ffff ffff ......cG.cG....
00000040: ffff ffff ff63 47ff ffff ffff ffff ffff .........cG..
00000050: ffff ffff 6347 ffff ffff ffff ffff ffff .........cG........
00000060: ffff ffff 47ff ffff ffff ffff ffff ffff 0000 ...cG........
00000070: 0000 0000 0000 0000 0000 0000 0000 0000 0000 0000 0000 0000 0000
```

Good. Now let’s map the contents of the image, both header information and the sequence of pixels:

```sh
(poke) var ppl = byte @ 3#B
(poke) var lines = byte @ 4#B
(poke) var image_data = byte[3][ppl][lines] @ 5#B
```

Let’s modify the image. Since the dimensions of the new image are exactly the same, the header remains the same. It is the pixel sequence that is different. We basically need to turn the pixels at coordinates (4,2), (5,3) and (6,3) from background pixels to foreground pixels.

Remember how we would change the value of some integer in the IO space? First, we would map it into a variable, change the value, and then poke it back to the IO space. Something like this:

```sh
(poke) var n = int @ offset
(poke) n = n + 1
(poke) int @ offset = n
```

This three-steps process is necessary because in the \( n = n + 1 \) above we are modifying the value of the variable \( n \), not the integer actually stored at offset \( offset \) in the current IO space. Therefore we have to explicitly poke it back if we want the IO space to be updated as well.
Array values (and, as we shall see, other “composited” values) are different: when they are the result of the application of the map operator, the resulting values are mapped themselves.

When a Poke value is mapped, updating their elements have a side effect: the area corresponding to the updated element, in whatever IO space it is mapped on, is updated as well!

Why is this? The map operator, regardless of the kind of value it is mapping, always returns a copy of the value found stored in the IO space. We already saw how this worked with integers. However, in Poke values are copied around using a mechanism called “shared value”. This means that when a composite value like an array is copied, its elements are shared by both the original value and the new value.

We can depict this graphically for better understanding. A Poke array like:

```plaintext
(poke) var a = [1, 2, 3]
```

is stored in memory like this:

```
+---+---+---+
 a | 1 | 2 | 3 |
+---+---+---+
```

If we make a copy of the array in another variable b:

```plaintext
(poke) var b = a
```

we get

```
+---+---+---+ +---+---+---+
 a | 1 | 2 | 3 | b | 1 | 2 | 3 |
+---+---+---+ +---+---+---+
```

Note how each of the integer elements has been copied to the new value. The resulting two arrays can then be modified independently:

```plaintext
(poke) a[1] = 5
```

resulting in:

```
+---+---+---+ +---+---+---+
 a | 1 | 5 | 3 | b | 1 | 2 | 3 |
+---+---+---+ +---+---+---+
```

However, consider the following array whose elements are also arrays:

```plaintext
(poke) var a = [[1, 2], [3, 4], [5, 6]]
```

This array is stored in memory like this:

```
+-----------+ +-----------+
 | 1 | 2 |   | 3 | 4 |   | 5 | 6 |
+-----------+ +-----------+
```

If now we make a copy of the same array into another variable b:

```plaintext
(poke) var b = a
```
The elements of the array are copied “by shared value”, i.e.

```
+---+---+---+ +---+---+---+
|  a | | | |  b | | | |
+---+---+---+ +---+---+---+
  | | | +---+---+ | | |
  | | +---| 5 | 6 |---+ | |
  | | +---+---+ |
  | | | |
  | | +---+---+ |
  | +-------| 3 | 4 |-------+ |
  | +---+---+ |
  | |
  | +---+---+ |
+-----------| 1 | 2 |-----------+
+---+---+
```

The elements are indeed shared between the original array and the copy! If now we modify any of the shared values, this will be reflected in both containing values:

```
(poke) a[1][1] = 9
(poke) a
[[1,2],[3,9],[5,6]]
```

```
(poke) b
[[1,2],[3,9],[5,6]]
```

or graphically:

```
+---+---+---+ +---+---+---+
|  a | | | |  b | | | |
+---+---+---+ +---+---+---+
  | | | +---+---+ | | |
  | | +---| 5 | 6 |---+ | |
  | | +---+---+ |
  | | | |
  | | +---+---+ |
  | +-------| 3 | 9 |-------+ |
  | +---+---+ |
  | |
  | +---+---+ |
+-----------| 1 | 2 |-----------+
+---+---+
```

Back to our image, it follows that if we wanted to change the color of some SBM pixel stored at offset `offset`, we would do this:

```
(poke) var a = byte[3] @ offset
(poke) a[1] = 10
```

There is no need to poke the array back explicitly: the side effect of assigning 10 to a[1] is that the byte at offset `offset+1` is poked.

Generally speaking, mapped values can be handled in exactly the same way than non-mapped values. This is actually a very central concept in poke. However, it is possible to check whether a given value is mapped or not using the `mapped` attribute.

As we said, simple values such as integers and strings are never mapped, regardless of where they come from. Both `ppl` and `lines` are integers, therefore:

```
(poke) ppl\'mapped
```
(poke) lines 'mapped
0

However, image_data is an array that was the result of the application of a map operator, so:

(poke) image_data 'mapped
1

When a value is mapped, you can ask for the offset where it is mapped, and the IO space where it is mapped, using the attributes 'offset and 'ios respectively. Therefore:

(poke) image_data 'ios
1
(poke) image_data 'offset
40UL#b

In other words, image_data is mapped in the IO space with id 1 (the *scratch* buffer) at offset 40 bits, or 5 bytes. We already knew that, because we mapped the image data ourselves, but in other situations these attributes are most useful. We shall see how later.

Well, at this point it should be clear how to paint pixels. First, let’s define our background and foreground pixels:

- (poke) var bga = [255UB, 255UB, 255UB]
- (poke) var fga = [255UB, 99UB, 71UB]

Then, we just update the pixels in the image data using the right coordinates:

- (poke) image_data[4][2] = fga
- (poke) image_data[5][3] = fga
- (poke) image_data[6][3] = fga
- (poke) dump

4.3.3 Cropping the R

Looking at our new image, we realize that the first and the last column are all background pixels. We are aware that the recutils project is always short of resources, so we would like to modify the image to remove these columns, cropping it so it looks like this:

<table>
<thead>
<tr>
<th>0</th>
<th>1</th>
<th>2</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>*</td>
<td>*</td>
</tr>
<tr>
<td>1</td>
<td>*</td>
<td>*</td>
</tr>
<tr>
<td>2</td>
<td>*</td>
<td>*</td>
</tr>
<tr>
<td>3</td>
<td>*</td>
<td>*</td>
</tr>
<tr>
<td>4</td>
<td>*</td>
<td>*</td>
</tr>
<tr>
<td>5</td>
<td>*</td>
<td>*</td>
</tr>
<tr>
<td>6</td>
<td>*</td>
<td>*</td>
</tr>
</tbody>
</table>

In order to perform this operation we need to rework the stream of pixels to reflect the desired result, and then to update the header metadata accordingly.
4.3.4 Shortening and Shifting Lines

Let’s think in term of lines. In the original image, each line has 5 pixels, that we can enumerate as:

```
+----+----+----+----+----+
line | p0 | p1 | p2 | p3 | p4 |
+----+----+----+----+----+
```

What we want is to crop out the first and the last column, so the resulting line would look like:

```
+----+----+----+
line | p1 | p2 | p3 |
+----+----+----+
```

Let’s get the first line from the original image_data:

```
(poke) var l0 = image_data[0]
(poke) l0
[[255UB, 255UB, 255UB], [255UB, 99UB, 71UB], ...]
```

We could create the corresponding cropped line, by doing something like this:

```
(poke) var cl0 = [l0[1], l0[2], l0[3]]
```

And the same for the other lines. However, Poke provides a better way to easily obtain sub portions of arrays. It is called trimming. Given an array like the line 10, we can obtain the desired portion of it by issuing:

```
(poke) 10[1:4]
[[255UB, 99UB, 71UB], [255UB, 99UB, 71UB]]
```

Note how the limits of the semi-open interval specified in the trim reflect array indexes, and hence they are 0 based. Also, the left limit is closed and the right limit is open. The result of an array trimming is always another array, which may be empty:

```
(poke) 10[1:3]
[[255UB, 99UB, 71UB]]
```

Armed with this new operation, we can very easily mount the sequence of pixels for our cropped image:

```
(poke) var l0 = image_data[0]
(poke) var l1 = image_data[1]
(poke) var l2 = image_data[2]
(poke) var l3 = image_data[3]
(poke) var l4 = image_data[4]
(poke) var l5 = image_data[5]
```

And then update the lines in the mapped image data:

```
(poke) image_data[0] = 10[1:4]
(poke) image_data[0] = 11[1:4]
(poke) image_data[0] = 12[1:4]
(poke) image_data[0] = 13[1:4]
(poke) image_data[0] = 14[1:4]
(poke) image_data[0] = 15[1:4]
```

4.3.5 Updating the Header

The last step is to update the header to reflect the new dimensions of the image:

```
(poke) byte[] @ 0#B = ['S', 'B', 'M']
(poke) byte @ 3#B = 3
(poke) byte @ 4#B = 7
```
And we are done. Note how this time we wrote the magic bytes as an array, to save some typing and silly manual offset arithmetic. You may have noticed that the type specifier we used this time in the map is `byte[]` instead of `byte[3]`. This type specifier denotes an array of any number of bytes, which certainly includes arrays of three bytes, like in the example.

### 4.3.6 Saving the Result

And finally, let’s write out the new file as `r.sbm`:

```latex
(poke) save :from 0#B :size 5#B + image_data'size :file "r.sbm"
```

### 4.4 Defining Types

#### 4.4.1 Naming your Own Abstractions

During the process of creating and manipulating SBM files we soon started talking about things like lines, pixel sequences, pixels, colors, and so on. What is more, very naturally we started thinking in terms of these entities: let’s drop this or that line, or let’s change the green component of this pixel.

Consider for example RGB colors. We know that each color is defined by three levels of light: red, green and blue. These components are also called color beams. Since each color beam has a range of 0 to 255, many formats, like SBM, use bytes to encode them.

Therefore, in the previous sections we used the type specifier `byte` when we needed to map RGB color beams, like in:

```latex
(poke) byte[3] @ 5#B
```

Recall that the mapping operation above means “map three bytes at the offset 5 bytes in the current IO space”. But what we really want is to map color beams, not bytes!

Poke provides a way to assign names to type specifiers:

```latex
(poke) type RGB_Color_Beam = byte
```

The definition above tells poke that a RGB color beam is composed of a byte, *i.e.* an unsigned 8-bit integer. Any type specifier can be used at the right side of the assignment sign, and also names of already defined types. From this point on, we can map in terms of color beams:

```latex
(poke) RGB_Color_Beam[3] @ 5#B
```

Meaning “map three RGB color beams at the offset 5 in the current IO space”.

Once a type is defined, the name can be used anywhere where a type specifier is expected.

By the way, we mentioned many times how `byte` is a synonym for `uint<8>`, `int` is a synonym for `int<32>` and so on. These synonyms are actually result of type definitions that are in the poke standard library. This library is loaded by poke at startup time.

#### 4.4.2 Abstracting the Structure of Entities

Since we didn’t know better, during our work with SBM images we had to remember how these entities were constructed from more simple entities such as bits and bytes, every time we needed to map them, or to poke them. For example, if we wanted to map a pixel at some particular offset, we had to issue the following command:

```latex
(poke) var pixel = byte[3] @ 5#B
```

Now that we made poke aware of what a RGB color beam is, we can rewrite the above as:

```latex
(poke) var pixel = RGB_Color_Beam[3] @ 5#B
```

This is better, but still adoleces from a big problem: what if at some point the SBM pixels get expanded to also have a transparency index, stored in a fourth byte? If that ever happens (and
will happen later in this book) then we would need to remember it before issuing commands like:

```
(poke) var image_data = RGB_Color_Beam[4][ppl][lines] @ 5#B
```

To avoid this problem, we define yet another type, this time describing the structure of a SBM pixel:

```
(poke) type SBM_Pixel = RGB_Color_Beam[3]
```

And then we can define `image_data` as a table of SBM pixels, instead of as a table of triplets of RGB color beams:

```
(poke) var image_data = SBM_Pixel[ppl][lines] @ 5#B
```

This later definition doesn’t need to be changed if we change the definition of what a SBM pixel is. This is called encapsulation and is a very useful abstraction in computing.

## 4.5 Pickles

### 4.5.1 poke Commands versus Poke Constructions

In Section 1.2 [Nomenclature], page 4, we mentioned that poke, the program, implements a domain specific programming language called Poke, with a big p. In the examples so far we have already used the Poke language, somewhat extensively, while interacting with the program using the REPL.

For example, in:

```
(poke) 10 + 2
```

We are giving poke a Poke expression `10 + 2` to be evaluated. Once the expression is evaluated, the REPL prints the resulting value for us.

Similarly, when we define a variable or a type with `var` and `type` respectively, we are providing poke definitions to be evaluated. When we assign a value to a variable we are actually providing a Poke statement to be executed.

So the REPL accepts poke commands, some of which happen to be Poke expressions, definitions or statements. But we also have used dot-commands like `.file` or `.info`. These dot-commands are not part of the Poke programming language.

Every time we insert a line in the REPL and hit `enter`, poke recognizes the nature of the line, and then does the right thing. If the line is recognized as a Poke expression, for example, the Poke compiler is used to compile the statement into a routine, that is executed by the Poke Virtual Machine. The resulting value is then printed for the benefit of the user.

### 4.5.2 Poke Files

Poke programs are basically a collection of definitions and statements, which most often than not are stored in files, which avoids the need to type them again and again. By convention, we use the `.pk` file extension when naming files containing Poke programs.

Remember how we defined the foreground and background pixels for `p.sbm` in the REPL?

```
(poke) var bga = [255UB, 255UB, 255UB]
(poke) var fga = [255UB, 99UB, 71UB]
```

Where `bga` is a white pixel and `fga` is a tomato colored pixel. We could write these definitions in a file `colors.pk` like this:

```
var white = [255UB, 255UB, 255UB];
var tomato = [255UB, 99UB, 71UB];
```

Note that variable definitions in Poke are terminated by a semicolon (\;) character, but we didn’t need to specify them when we issued the definitions in the REPL. This is because poke adds
the trailing semicolon for us when it detects a Poke construction requiring it is introduced in the REPL.

Another difference is that Poke constructions can span for multiple lines, like in most programming languages. For example, we could have the following variable definition in a file:

```pokemodule
var matrix = [[10, 20, 30],
              [40, 50, 60],
              [70, 80, 90]];
```

Once we have written our `colors.pk` file, how can we make poke aware of it? A possibility is to use the `load` construction:

```pokemodule
(load) load colors
```

Assuming a file named `colors.pk` exists in the current working directory, poke will load it and evaluate its contents. After this, we can use the colors:

```pokemodule
(load) tomato
[0xffUB, 0x63UB, 0x47UB]
```

Before, we would need to define these colors every time we would like to poke SBM files or, in fact, any RGB24 data. Now we just have to load the file `colors.pk` and use the variables defined there.

If you try to load a file whose name contains a dash character (`-`) you will get an error message:

```pokemodule
(load) load my-colors
<stdin>:1:8: error: syntax error, unexpected '-', expecting ';'
load my-colors;
```

This is because the argument to `load` is interpreted as a Poke identifier, and dash characters are not allowed in identifiers. To alleviate this problem, you can also specify the name of the file to load encoded in a string, line in:

```pokemodule
(load) load "my-colors.pk"
```

If you use this form of `load`, however, you are required to specify the complete name of the file, including the `.pk` file extension.

Since loading files is such a common operation, poke provides a dot-command `.load` that does auto-completion:

```pokemodule
(dot) .load my-colors.pk
```

Which is equivalent to `load "my-colors.pk"`.

Since `load` is part of the Poke language, it can also be used in Poke programs stored in files. We will explore this later.

### 4.5.3 Pickling Abstractions

In the last section we defined a couple of RGB colors `white` and `tomato` in a file called `colors.pk`. If we keep adding colors to the file, we may end with a nice collection of colors that are available to us at any time, by just loading the file.

Since there are many ways to understand the notion of “color”, and also many ways to implement these many notions, it would be better to be more precise and call our file `rgb24.pk`, since the notion of color we are using is of that RGB24. While are at it, let’s also rename the variables to reflect the fact they denote not just any kind of colors, but RGB24 colors:

```pokemodule
var rgb24_white = [255UB, 255UB, 255UB];
var rgb24_tomato = [255UB, 99UB, 71UB];
```

At this point, we can also add the definitions of a couple of types to our `rgb24.pk`:

```pokemodule
type RGB_Color_Beam = byte;
```
type RGB24_Color = RGB_Color_Beam[3];

var rgb24_white = [255UB, 255UB, 255UB];
var rgb24_tomato = [255UB, 99UB, 71UB];

Any time we want to manipulate RGB24 colors we can just load the file rgb24.pk and use these types and variables.

In poke parlance we call files like the above, that contain definitions of conceptually related entities, pickles. Pickles can be very simple, like the rgb24.pk sketched above, or fairly complicated like dwarf.pk.

It is common for pickles to load other pickles. For example, if we were to write a SBM pickle, we would load the RGB24 pickle from it:

load rgb24;

[... SBM definitions ...]

This way, when we load sbm from the repl, the dependencies get loaded as well.

GNU poke includes several already written pickles for commonly used file formats, and other domains. The load construction knows where these pickles are installed, so in order to load the pickle to manipulate ELF files, for example, all you have to do is to:

(poke) load elf

4.5.4 Exploring Pickles

As we have seen, a pickle provides Poke variables, types and functions related to some definite domain. Let’s say we are interested in editing an ELF file. We know that GNU poke comes with a pre-installed pickle named elf.pk. We can load it like this:

(poke) load elf

By convention, the entities provided by a pickle foo.pk are usually prefixed like:

- Variables, units and functions are prefixed with foo_.
- Types are prefixed with Foo_.

Therefore, once the pickle is loaded we can use the .info dot-command in order to get a glimpse of the functionality provided by the pickle. See Section 23.13 [info command], page 121. Example:

(poke) .info variables elf
Name Declared at
elf_stb_names elf-common.pk:53
elf_stt_names elf-common.pk:72
elf_stv_names elf-common.pk:84

The above tells us that the elf.pk pickle provides these three variables. Types are way more interesting:

(poke) .info types Elf64
Name Declared at
Elf64_Ehdr elf-64.pk:184
Elf64_Off elf-64.pk:26
Elf64_SectionFlags elf-64.pk:130
Elf64_Shdr elf-64.pk:152
Elf64_RelInfo elf-64.pk:36
Elf64_Chdr elf-64.pk:85
Elf64_Rela elf-64.pk:61
Elf64_Phdr elf-64.pk:169
We immediately notice the Elf64_File. Looks like what we would need to map in order to access the entire ELF data in some given IO space (like a file.) We can ask for more details about it:

(poke) .info type Elf64_File
Class: struct
Name: Elf64_File
Complete: no
Fields:
Name Type
ehdr Elf64_Ehdr
shdr Elf64_Shdr[]
phdr Elf64_Phdr[]
Methods:
Name Type
get_section_name (offset<Elf_Word,8>)string
get_symbol_name (Elf64_Shdr,,offset<Elf_Word,8>)string
get_sections_by_name (Elf_Word)Elf64_Shdr[]

We see that an Elf64_File has three fields, and the nature of these files: a header ehdr, an array of section headers shdr and an array of program headers phdr.

The type description above also lists the methods defined in the type. Looking at the method name and its type is very usually revealing enough to use it. For example, we see that get_sections_by_name returns an array of section headers, characterized by some given section name:

(poke) var elf = Elf64_File @ 0#B
(poke) elf.get_sections_by_name (".text")
[Elf64_Shdr {
  sh_name=0x1bU#B,
  sh_type=0x1U,
  sh_flags=#<ALLOC,EXECINSTR>,
  sh_addr=0x0UL#B,
  sh_offset=0x40UL#B,
  sh_size=0xbUL#B,
  sh_link=0x0U,
  sh_info=0x0U,
  sh_addralign=0x1UL,
  sh_entsize=0x0UL#b
}]

We immediately notice the Elf64_File. Looks like what we would need to map in order to access the entire ELF data in some given IO space (like a file.) We can ask for more details about it:
Ultimately, of course the best way to see what a pickle provides is to go read its source code.

4.5.5 Startup

When poke starts it loads the file .pokerc located in our home directory, if it exists. This initialization file contains poke commands, one per line.

If we wanted to get some Poke file loaded at startup, we could do it by adding a load command to our .pokerc. For example:

```plaintext
# My poke configuration - jemarch
[...]
.load ~/poke.d/mydefs.pk
```

4.6 Poking Structs

4.6.1 Heterogeneous Related Data

Let’s recap the structure of the header of a Stupid BitMap:

```
+-------+-------+-------+-------+-------+
| 'S'  | 'B'  | 'M'  | ppl  | lines |
+-------+-------+-------+-------+-------+
```

The header is composed of five fields, which actually compose three different logical fields: a magic number, the number of pixels per line, and the number of lines.

We could of course abstract the header using an array of five bytes, like this:

```plaintext
type SBM_Header = byte[5];
```

However, this would not capture the properties of the fields themselves, which would need to be remembered by the user: which of these five bytes correspond to the magic number? Is the pixels per line number signed or unsigned? etc.

Poke provides a much better way to abstract collections of heterogeneous data: struct types. Using a struct type we can abstract the SBM header like this:

```plaintext
type SBM_Header =
struct
{
    byte[3] magic;
    uint<8> ppl;
    uint<8> lines;
}
```

Note how the struct has three named fields: magic, ppl and lines. magic is an array of three bytes, while ppl and lines are both unsigned integers.

4.6.2 Mapping Structs

Once defined, struct types can be referred by name. For example, we can map the SBM header at the beginning of our file p.sbm like this:

```plaintext
(poke) SBM_Header @ 0#B
SBM_Header {
    magic=[0x53UB,0x42UB,0x4dUB],
    ppl=0x5UB,
    lines=0x7UB
}
```
The value resulting from the mapping is a struct value. The fields of struct values are accessed using the familiar dot-notation:

```
(poke) var header = SBM_Header @ 0#B
(poke) header.ppl * header.lines
35UB
```

The total number of pixels in the image is 35. Note how both `header.ppl` and `header.lines` are indeed unsigned byte values, and thus the result of the multiplication is also an unsigned byte. This could be problematic if the image contained more than 255 pixels, but this can be prevented by using a cast:

```
(poke) header.ppl as uint * header.lines
35U
```

Now the second operand `header.lines` is promoted to a 32-bit unsigned value before the multiplication is performed. Consequently, the result of the operation is also 32-bit wide (note the suffix of the result.)

### 4.6.3 Modifying Mapped Structs

Remember when we wanted to crop a SBM image by removing the first and last row? We updated the header in a byte by byte manner, like this:

```
(poke) byte @ 3#B = 3
(poke) byte @ 4#B = 7
```

Now that we have the header mapped in a variable, updating it is much more easy and convenient. The dot-notation is used to update the contents of a struct field, by placing it at the left hand side of an assignment:

```
(poke) header.ppl = 3
(poke) header.lines = 7
```

This updates the pixel per line and the number of lines, in the IO space:

```
(poke) dump :size 5#B
76543210 0011 2233 4455 6677 8899 aabb ccdd eeff 0123456789ABCDEF
00000000: 5342 4D03 07 SBM..
```

### 4.7 How Structs are Built

First we need to define some structure to use as an example. Let’s say we are interesting in poking Packets, as defined by the Packet Specification 1.2 published by the Packet Foundation (none less).

In a nutshell, each Packet starts with a byte whose value is always `0xab`, followed by a byte that defines the size of the payload. A stream of bytes conforming the payload follows, themselves followed by another stream of the same number of bytes with “control” values.

We could translate this description into the following Poke struct type definition:

```go
type Packet =
  struct
  {
    byte magic == 0xab;
    byte size;
    byte[size] payload;
    byte[size] control;
  };
```

There are some details described by the fictitious Packet Specification 1.2 that are not covered in this simple definition, but we will be attending to that later in this manual.
So, given the definition of a struct type like Packet, there are only two ways to build a struct value in Poke.

One is to map it from some IO space. This is achieved using the map operator:

```plaintext
(poke) Packet @ 12#B
Packet {
    magic == 0xab,
    size = 2,
    payload = [0x12UB,0x30UB],
    control = [0x1UB,0x1UB]
}
```

The expression above maps a Packet starting at offset 12 bytes, in the current IO space. See the Poke manual for more details on using the map operator.

The second way to build a struct value is to construct one, specifying the value to some, all or none of its fields. It looks like this:

```plaintext
(poke) Packet {size = 2, payload = [1UB,2UB]}
Packet {
    magic == 0xab,
    size = 2,
    payload = [0x1UB,0x2UB],
    control = [0x0UB,0x0UB]
}
```

In either case, building a struct involves to determine the value of all the fields of the struct, one by one. The order in which the struct fields are built is determined by the order of appearance of the fields in the type description.

In our example, the value of `magic` is determined first, then `size`, `payload` and finally `control`. This is the reason why we can refer to the values of previous fields when defining fields, such as in the size of the `payload` array above, but not the other way around: by the time `payload` is mapped or constructed, the value of `size`, has already been mapped or constructed.

What happens behind the curtains is that when poke finds the definition of a struct type, like `Packet`, it compiles two functions from it: a mapper function, and a constructor function. The mapper function gets as arguments the IO space and the offset from which to map the struct value, whereas the constructor function gets the template specifying the initial values for some, or all of the fields; reasonable default values (like zeroes) are used for fields for which no initial values have been specified.

These functions, mapper and constructor, are invoked to create fresh values when a map operator @ or a struct constructor is used in a Poke program, or at the poke prompt.

### 4.8 Variables in Structs

Fields are not the only entity that can appear in the definition of a struct type.

Suppose that after reading more carefully the Packet Specification 1.2 (that spans for several thousand of pages) we realize that the field `size` doesn’t really store the number of bytes of the payload and control arrays, like we thought initially. Or not exactly: the Packet Foundation says that if `size` has the special value 0xff, then the size is zero.

We could of course do something like this:

```plaintext
type Packet =
    struct
    {
        byte magic == 0xab;
    }
```
byte size;

byte[size == 0xff ? 0 : size] payload;
byte[size == 0xff ? 0 : size] control;

};

However, we can avoid replicating code by using a variable instead:

type Packet =
struct
{
  byte magic == 0xab;
  byte size;

  var real_size = (size == 0xff ? 0 : size);

  byte[real_size] payload;
  byte[real_size] control;
};

Note how the variable can be used after it gets defined. In the underlying process of mapping or constructing the struct, the variable is incorporated into the lexical environment. Once defined, it can be used in constraint expressions, array sizes, and the like. We will see more about this later.

Incidentally, it is of course possible to use global variables as well. For example:

var packet_special = 0xff;
type Packet =
struct
{
  byte magic == 0xab;
  byte size;

  var real_size = (size == packet_special ? 0 : size);

  byte[real_size] payload;
  byte[real_size] control;
};

In this case, the global packet_special gets captured in the lexical environment of the struct type (in reality in the lexical environment of the implicitly created mapper and constructor functions) in a way that if you later modify packet_special the new value will be used when mapping/constructing new values of type Packet. Which is really cool, but let’s not get distracted from the main topic... :)

4.9 Functions in Structs

Further reading of the Packet Specification 1.2 reveals that each Packet has an additional crc field. The content of this field is derived from both the payload bytes and the control bytes.

But this is no vulgar CRC we are talking about. On the contrary, it is a special function developed by the CRC Foundation in partnership with the Packet Foundation, called superCRC (patented, TM).

Fortunately, the CRC Foundation distributes a pickle supercrc.pk, that provides a calculate_crc function with the following spec:

fun calculate_crc = (byte[] data, byte[] control) int:
So let’s use the function like this in our type, after loading the supercrc pickle:

```go
load supercrc;

type Packet =
  struct
  {
    byte magic == 0xab;
    byte size;

    var real_size = (size == 0xff ? 0 : size);

    byte[real_size] payload;
    byte[real_size] control;

    int crc = calculate_crc (payload, control);
  };
```

However, there is a caveat: it happens that the calculation of the CRC may involve arithmetic and division, so the CRC Foundation warns us that the `calculate_crc` function may raise `E_div_by_zero`. However, the Packet 1.2 Specification tells us that in these situations, the `crc` field of the packet should contain zero. If we used the type above, any exception raised by `calculate_crc` would be propagated by the mapper/constructor:

```go
(poke) Packet @ 12#B
unhandled division by zero exception
```

A solution is to use a function that takes care of the extra needed logic, wrapping `calculate_crc`:

```go
load supercrc;

type Packet =
  struct
  {
    byte magic == 0xab;
    byte size;

    var real_size = (size == 0xff ? 0 : size);

    byte[real_size] payload;
    byte[real_size] control;

    fun corrected_crc = int:
    {
      try return calculate_crc (payload, control);
      catch if E_div_by_zero { return 0; }
    }

    int crc == corrected_crc;
  };
```

Again, note how the function is accessible after its definition. Note as well how both fields and variables and other functions can be used in the function body. There is no difference to define variables and functions in struct types than to define them inside other functions or in the top-level environment: the same lexical rules apply.
4.10 Struct Methods

At this point you may be thinking something on the line of “hey, since variables and functions are also members of the struct, I should be able to access them the same way than fields, right?”.

So you will want to do:

(poke) var p = Packet 12#B
(poke) p.real_size
(poke) p.corrected_crc

But sorry, this won’t work.

To understand why, think about the struct building process we sketched above. The mapper and constructor functions are derived/compiled from the struct type. You can imagine them to have prototypes like:

Packet_mapper (IOspace, offset) -> Packet value
Packet_constructor (template) -> Packet value

You can also picture the fields, variables and functions in the struct type specification as being defined inside the bodies of Packet_mapper and Packet_constructor, as their contents get mapped/constructed. For example, let’s see what the mapper does:

Packet_mapper:

. Map a byte, put it in a local ‘magic’.
. Map a byte, put it in a local ‘size’.
. Calculate the real size, put it in a local ‘real_size’.
. Map an array of real_size bytes, put it in a local ‘payload’.
. Map an array of real_size bytes, put it in a local ‘control’.
. Compile a function, put it in a local ‘corrected_crc’.
. Map a byte, call the function in the local ‘corrected_crc’, complain if the values are not the same, otherwise put the mapped byte in a local ‘crc’.
. Build a struct value with the values from the locals ‘magic’, ‘size’, ‘payload’, ‘control’ and ‘crc’, and return it.

The pseudo-code for the constructor would be almost identical. Just replace “map a byte” with “construct a byte”.

So you see, both the values for the mapped fields and the values for the variables and functions defined inside the struct type end as locals of the mapping process, but only the values of the fields are actually put in the struct value that is returned in the last step.

This is where methods come in the picture. A method looks very similar to a function, but it is not quite the same thing. Let me show you an example:

load supercrc;

type Packet =
    struct
    {  
        byte magic == 0xab;
        byte size;

        var real_size = (size == 0xff ? 0 : size);

        byte[real_size] payload;
        byte[real_size] control;
    }
fun corrected_crc = int:
{
    try return calculate_crc (payload, control);
    catch if E_div_by_zero { return 0; }
}

int crc = corrected_crc;

method c_crc = int:
{
    return corrected_crc;
}

We have added a method c_crc to our Packet struct type, that just returns the corrected superCRC (patented, TM) of a packet. This can be invoked using dot-notation, once a Packet value is mapped/constructed:

(poke) var p = Packet 12#B
(poke) p.c_crc
0xdeadbeef

Now, the important bit here is that the method returns the corrected crc of a Packet. That’s it, it actually operates on a Packet value. This Packet value gets implicitly passed as an argument whenever a method is invoked.

We can visualize this with the following “pseudo Poke”:

method c_crc = (Packet SELF) int:
{
    return SELF.corrected_crc;
}

Fortunately, poke takes care to recognize when you are referring to fields of this implicit struct value, and does The Right Thing(TM) for you. This includes calling other methods:

method foo = void: { ... }
method bar = void:
{
    [...] foo;
}

The corresponding “pseudo-poke” being:

method bar = (Packet SELF) void:
{
    [...] SELF.foo ();
}

It is also possible to define methods that modify the contents of struct fields, no problem:

var packet_special = 0xff;

type Packet =
struct
{
    byte magic == 0xab;
    byte size;
Chapter 4: Structuring Data

method set_size = (byte s) void:
{
    if (s == 0)
        size = packet_special;
    else
        size = s;
}

This is what is commonly known as a setter. Note, incidentally, how a method can also use regular variables. The Poke compiler knows when to generate a store in a normal variable such as packet_special, and when to generate a set to a SELF field.

Given the different nature of the variables, functions and methods, there are a couple of restrictions:

- Functions can’t set fields defined in the struct type.

  This will be rejected by the compiler:

  ```
  type Foo =
    struct
    { int field;
      fun wrong = void: { field = 10; }
    }
  ;
  ```

  Remember the construction/mapping process. When a function accesses a field of the struct type like in the example above, it is not doing one of these pseudo SELF.field = 10.

  Instead, it is simply updating the value of the local created in this step in Foo_mapper:

  ```
  Foo_mapper:
  . Map an int, put it in a local 'field'.
  . [...]
  ```

  Setting that local would impact the mapping of the subsequent fields if they refer to field (for example, in their constraint expression) but it wouldn’t actually alter the value of the field field in the struct value that is created and returned from the mapper!

  This is very confusing, so we just disallow this with a compiler error “invalid assignment to struct field”, for your own sanity 8-)

- Methods can’t be used in field constraint expressions, nor in variables or functions defined in a struct type.

  How could they be? The field constraint expressions, the initialization expressions of variables, and the functions defined in struct types are all executed as part of the mapper/constructor and, at that time, there is no struct value yet to pass to the method.

  If you try to do this, the compiler will greet you with an “invalid reference to struct method” message.

  Something to keep in mind about methods is that they can destroy the integrity of the data stored in a struct. Consider for example the following struct type:

  ```
  type Packet =
    struct
    { byte magic == 0xab;
      byte size : size <= 4096;
  ```
method set_size = (byte s) void:
{
    if (s == 0)
        size = packet_special;
    else
        size = s;
}
);

Observe how this new version of Packet has an additional constraint that specifies size should not exceed 4096. However, when the method set_size is executed the constraints are not checked again. This is useful at times, but can also lead to unintended data corruption.

A solution for this problem is to make methods aware of the restrictions. Like in this case:

```plaintext
type Packet =
    struct
    {
        byte magic == 0xab;
        byte size : size <= MAXSIZE;
    };

type Packet =
    struct
    {
        var MAXSIZE = 4096;

        byte magic == 0xab;
        byte size : size <= MAXSIZE;
        [...]}

method set_size = (byte s) void:
{
    if (s == 0)
        size = packet_special;
    else if (s > MAXSIZE)
        raise E_inval;
    else
        size = s;
}
);
```

Note how we use a variable MAXSIZE in order to avoid hard-coding 4096 twice in the struct definition.

Occasionally it is useful to access to additional properties of a containing struct or union in a method, other than its fields. For this purpose it is possible to refer explicitly to the struct using the SELF keyword. Note that the value referred has type any.

For example, this is how we could print the name of the current alternative in a pretty-printer for an union:

```plaintext
type Foo =
    union int<32>
    {
        int<32> One == 1;
        int<32> Two == 2;
        method _print = void:
        {
            printf ("%s (%v)", SELF'ename (0), SELF'elem (0));
        }
    }
```
4.11 Padding and Alignment

It is often the case in binary formats that certain elements are separated by some data that is not really used for any meaningful purpose other than occupy that space. The reason for keeping that space varies from case to case; sometimes to reserve it for future use, sometimes to make sure that the following data is aligned to some particular alignment. This is known as padding. There are several ways to implement padding in GNU poke. This article shows these techniques and discusses their advantages and disadvantages.

4.11.1 Esoteric and exoteric padding

Padding is the technique of keeping some amount of space between two different elements in some data stream. GNU poke provides two different ways to express sequences of data elements: the fields of a struct type, which are defined one after the other, and elements in an array.

We call adding space between two struct fields esoteric (or internal) padding.

We call adding space between two array elements exoteric (or external) padding.

The following sections contain examples of the two kinds of padding and how to better handle them in Poke.

4.11.2 Reserved fields

People designing binary encoded formats tend to be cautious and try to avoid future backward incompatibilities by keeping some unused fields that are reserved for future use. This is the first kind of padding we will be looking at, and is particularly common in structures like headers.

See for example the header used to characterize compressed section contents in ELF files:

```c
type Elf64_Chdr =
    struct
        Elf_Word ch_type;
        Elf_Word ch_reserved;
        offset<Elf64_Xword,B> ch_size;
        offset<Elf64_Xword,B> ch_addralign;
    
where the ch_reserved field is reserved for future use. When the time comes the space occupied by that field (32 bits in this case) will be used to hold additional data in the form of one or more fields. The idea is that implementations of the older formats will still work.

The most obvious way to handle this in Poke is using a named field like ch_reserved above. This field will be decoded/encoded by poke when constructing/mapping/writing struct values of this type, and will be available to the user as chdr.ch_reserved.

Sometimes reserved space is required to be filled with certain data values, such as zeroes. This may be to simplify things, or to force data producers to initialize the memory in order to avoid potential leaking of sensible information. In these cases we can use Poke initial values:

```c
    type Elf64_Chdr =
        struct
            Elf_Word ch_type;
            Elf_Word ch_reserved == 0;
            offset<Elf64_Xword,B> ch_size;
            offset<Elf64_Xword,B> ch_addralign;
        
This will make poke to check that ch_reserved is zero when constructing or mapping headers for compressed sections raising a constraint violation exception otherwise. It will also make poke to make sure ch_reserved to 0 when constructing Elf64_Chdr struct values:
An alternative way to characterize reserved space in Poke is to use anonymous fields. For example:

```go
type Elf64_Chdr =
  struct
  {
    Elf_Word ch_type;
    Elf_Word;
    offset<Elf64_Xword,B> ch_size;
    offset<Elf64_Xword,B> ch_addralign;
  };
```

Using Poke anonymous fields to implement reserved fields has at least two advantages. First, the user cannot anymore temper with the data in the reserved space in an easy way, i.e. `chdr.ch_reserved = 666` is no longer valid. Second, the printed representation of anonymous struct fields is more compact and denotes better than the involved space is not to be messed with:

```go
(poke) Elf64_Chdr {}
Elf64_Chdr {
  ch_type=0x0U,
  0x0U,
  ch_size=0x0UL#B,
  ch_addralign=0x0UL#B
}
```

A disadvantage of using anonymous fields is that you cannot specify constraint expressions for them, nor initial values. At some point we will probably add syntax to declare certain struct fields as read-only.

At this point, it is important to note that anonymous fields are still encoded/decoded by poke every time the struct value is mapped or written, exactly like regular fields. Therefore using them doesn’t pose any advantage in terms of performance.

### 4.11.3 Payloads

The reserved fields discussed in the previous section are most often discrete units like words, double-words, and the like, they are usually of some fixed size, and they are used to delimit some space that is not to be used.

Another kind of padding happens when an entity contains space to be used to store some kind of payload whose contents are not determined. This would be such an example:

```go
type Packet =
  struct
  {
    offset<uint<32>,B> payload_size;
    byte[payload_size] payload;
    int flags;
  };
```

In this example we are using a `payload` field which is an array of bytes. The size of the payload is determined by the packet header, and the contents are not determined. Of course this assumes that the payload sizes are divisible in whole bytes; a bit-oriented format may need to use an array of bits instead.

This approach of using a byte (or bit) array like in the example above has the advantage of providing a field with the bytes (or bits) to the user, for inspection and modification:

```go
(poke) packet.payload
```
The user can still map whatever payload structure in that space using the attributes of a mapped Packet. For example, if the packet contains an array of ULEB128 numbers, we could do:

\[
\text{var numbers = ULEB128[packet.payload'size] @ packet.payload'offset}
\]

But this approach has a disadvantage: every time the packet structure is mapped or written the entire payload array gets decoded and encoded. If the payloads are big enough (think about the data blocks of a file described by a file system i-node for example) this can be a big problem in terms of performance.

Another problem of using byte (or bit) arrays for payloads is that the printed representation of the struct values include the contents of the arrays, and most often the user won’t be interested in seeing that:

\[
\text{Packet{ payload_size = 23#B }
\text{Packet{ payload_size=0x17U#B, payload=[0x0UB,0x0UB,0x0UB,0x0UB,0x0UB,...], flags=0x0}
\}
\]

Another alternative is to implement the padding implied by a payload using field labels:

\[
\text{type Packet =
struct
\{
  offset<uint<32>,B> payload_size;
  int flags @ OFFSET + payload_size;
\};}
\]

Note how a payload field no longer exists in the struct type, and the field flags is defined to start at offset OFFSET + payload_size. This way no explicit array is encoded/decoded when manipulating Packet values:

\[
\text{(poke) Packet { payload_size = 500#Mb }
Packet{
  payload_size=62500000U#B @ OUL#b,
  flags=0 @ 4000000032UL#b
} @ 0UL#b}
\]

In this example we used the omaps option, which asks poke to print the offsets of the fields. The offset of flags is 4000000032 bits, or 500 megabytes:

\[
\text{(poke) 4000000032UL #b/#MB 500UL}
\]

Mapping this new Packet involves reading and decoding five bytes, for the payload_size and flags only. This is clearly much faster and avoids unneeded IO.

However you may be wondering, if there is no explicit payload field, how to access the payload space? A way is to define a method to the struct to provide the payload attributes:

\[
\text{type Packet =
struct
\{
  offset<uint<32>,B> payload_size;
  var payload_offset = OFFSET;
  int flags @ OFFSET + payload_size;
\}
\]
method get_payload_offset = off64:
{
   return payload_offset;
}
);

Note how we captured the offset of the payload using a variable in the strict type definition. Returning OFFSET in get_payload_offset wouldn’t work for obvious reasons: in the body of the method OFFSET evaluates to the end of flags in this case.

Using this method you can easily access the payload (again as an array of ULEB128 numbers) like this:

```
var numbers = ULEB128[packet.payload_size @ packet.get_payload_offset
```

Finally, using labels for this purpose makes the printed representation of the struct values more readable by not including the payload bytes in it:

```
(poke) Packet {}
Packet {
   payload_size=0x0U#B,
   flags=0x0
}
```

### 4.11.4 Aligning struct fields

Another kind of esoteric padding happens when certain fields in entities are required to be aligned to some particular alignment. For example, suppose that the flags field in the packets used in the previous sections is required to always be aligned to 4 bytes regardless of the size of the payload. This would be a common requirement if the format is intended to be implemented in systems where data is to be accessed using its “natural” alignment.

Using explicit fields for both the payload and the additional padding, we could come with:

```
type Packet =
   struct
   {
      offset<
         uint<32>,B>
         payload_size;
      byte[payload_size] payload;
      byte[alignto (OFFSET, 4#B)] padding;
      int flags;
   };
```

Where alignto is a little function defined in the Poke standard library, like this:

```
fun alignto = (uoff64 offset, uoff64 to) uoff64:
{
   return (to - (offset % to)) % to;
}
```

Alternatively, using the labels approach (which is generally better as we discussed in the last section) the definition would become:

```
type Packet =
   struct
   {
      offset<
         uint<32>,B>
         payload_size;
      var payload_offset = OFFSET;
      int flags @ OFFSET + payload_size + alignto (payload_size, 4#B);
```

method get_payload_offset = off64:
    {
        return payload_offset;
    }
};

In this case, the payload space is still completely characterized by the payload_size field and the get_payload_offset method.

4.11.5 Padding array elements

Up to now all the examples of padding we have shown are in the category of esoteric or internal padding, i.e. it was intended to add space between fields of some particular entity.

However, sometimes we want to specify some padding between the elements of a sequence of entities. In Poke this basically means an array.

Suppose we have a simple file system that is conformed by a sequence of inodes. The contents of the file system have the following form:

```
+-----------------+
| inode |
+-----------------+
:     :
:     :
+-----------------+
| inode |
+-----------------+
:     :
:     :
+-----------------+
| data  |
+-----------------+
| inode |
+-----------------+
:     :
:     :
+-----------------+
| data  |
+-----------------+
| ...   |
```

That’s it, each inode describes a block of data of variable size that immediately follows. Then more pairs of inode-data follow until the end of the device. However, a requirement is that each inode has to be aligned to 128 bytes.

Let’s start by writing a simple type definition for the inodes:

```
type Inode =
struct
    { string filename;
      int perms;
      offset<uint<32>,B> data_size;
    };
```

This definition is simple enough, but it doesn’t allow us to just map an array of inodes like this:

```
(poke) Inode[] 0#B
```

We could of course add the data and padding explicitly to the inode structure:

```
type Inode =
struct
    { string filename;
      int perms;
```
Then we could just map \textbf{Inode[]} \@ 0\#B and we would get the expected result.

But this is not a good idea. On one hand because, as we know, this would imply mapping the full file system data byte by byte, and that would be very very slow. On the other hand, because the data is not part of the inode, conceptually speaking.

A better solution is to use this idiom:

\begin{verbatim}
type Inode =
    struct
        string filename;
        int perms;
        offset<uint<32>,B> data_size;

        byte[0] \@ OFFSET + data_size + alignto (data_size, 128#B);
    }
\end{verbatim}

This uses an anonymous field at the end of the struct type, of size zero, located at exactly the offset where the data plus padding would end in the version with explicit fields.

This latter solution is fast and still allows us to get an array of inodes reflecting the whole file system with:

\begin{verbatim}
(poke) var inodes = Inode[] \@ 0\#B
\end{verbatim}

Like in the previous sections, a method \texttt{=get\_data\_offset=} can be added to the struct type in order to allow accessing the data blocks corresponding to a given inode.

\section*{4.12 Dealing with Alternatives}

\subsection*{4.12.1 BSON}

BSON\textsuperscript{2} is a binary encoding for JSON documents. The top-level entity described by the spec is the \textbf{document}, which contains the total size of the document, a sequence of elements, and a trailing null byte.

We can describe the above in Poke with the following type definition:

\begin{verbatim}
type BSON_Doc =
    struct
        offset<int<32>,B> size;
        BSON_Elem[size - size'size - 1#B] elements;
        byte endmark : endmark == 0x0;
    }
\end{verbatim}

BSON elements come in different kinds, which correspond to the different types of JSON entities: 32-bit integers, 64-bit integers, strings, arrays, timestamps, and so on. Every element starts with a tag, which is a 8-bit unsigned integer that identifies its kind, and a name encoded as a NULL-terminated string. What comes next depends on the kind of element.

The following Poke type definition describes a subset of BSON elements, namely integers, big integers and strings:

\begin{verbatim}
type BSON_Elem =
\end{verbatim}

\footnote{\url{http://bsonspec.org/spec.html}}
struct
{
    byte tag;
    string name;

    union
    {
        int32 integer32 : tag == 0x10;
        int64 integer64 : tag == 0x12;
        BSON_String str : tag == 0x02;
    } value;
};

The union in BSON_Elem corresponds to the variable part. When poke decodes an union, it
tries to decode each alternative (union field) in turn. The first alternative that is successfully
decoded without raising a constraint violation exception is the chosen one. If no alternative can
be decoded, a constraint violation exception is raised.

To see this process in action, let’s use the BSON corresponding to the following little JSON
document:
{
    "name" : "Jose E. Marchesi",
    "age" : 40,
    "big" : 1076543210012345
}

Let’s take a look to the different elements:

(poke) .load bson.pk
(poke) var d = BSON_Doc 0#B
(poke) d.elements'length
0x3UL
(poke) d.elements[0]
BSON_Elem {
    tag=0x2UB,
    name="name",
    value=struct {
        str=BSON_String {
            size=0x11,
            value="Jose E. Marchesi",
            chars=[0x4aUB,0x6fUB,0x73UB,0x65UB...]
        }
    }
}
(poke) d.elements[1]
BSON_Elem {
    tag=0x10UB,
    name="age",
    value=struct {
        integer32=0x27
    }
}
(poke) d.elements[2]
BSON_Elem {
    tag=0x12UB,
name="big",
value=struct {
  integer64=0x3d31c3f9e3eb9L
}
}

Note how unions decode into structs featuring different fields. What field is available depends on the alternative chosen while decoding.

In the session above, d.elements[1].value contains an integer32 field, whereas d.elements[2].value contains an integer64 field. Let’s see what happens if we try to access the wrong field:

(poke) d.elements[1].value.integer64
unhandled invalid element exception

We get a run-time exception. This kind of errors cannot be caught at compile time, since both integer32 and integer64 are potentially valid fields in the union value.

4.12.2 Unions are Tagged

Unlike in C, Poke unions are tagged. Unions have their own lexical closures, and it is the captured values that determine what field is chosen at every time. Wherever the union goes, its tag accompanies it.

To see this more clearly, consider the following alternative Poke description of the BSON elements:

type BSON_Elem =
  union
  {
    struct
    {
      byte tag : tag == 0x10;
      string name;
      int32 value;
    } integer32;

    struct
    {
      byte tag : tag == 0x12;
      string name;
      int64 value;
    } integer64;

    struct
    {
      byte tag : tag == 0x12;
      string name;
      BSON_String value;
    } str;
  }

This description is way more verbose than the one used in previous sections, but it shows a few important properties of Poke unions.

First, the constraints guiding the decoding are not required to appear in the union itself: it is a recursive process. In this example, BSON_String could have constraints on it’s own, and these constraints will also impact the decoding of the union.
Second, there are generally many different ways to express the same plain binary using different type structures. This is no different than getting different parse trees from the same sequence of tokens using different grammars denoting the same language.

See how different a BSON element looks (and feels) using this alternative description:

```c
(poke) d.elements[0]
BSON_Elem {
    str=struct {
        tag=0x2UB,
        name="name",
        value=BSON_String {
            size=0x11,
            value="Jose E. Marchesi",
            chars=[0x4aUB,0x6fUB,0x73UB,0x65UB...]
        }
    }
}
(poke) d.elements[1]
BSON_Elem {
    integer32=struct {
        tag=0x10UB,
        name="age",
        value=0x27
    }
}
(poke) d.elements[2]
BSON_Elem {
    integer64=struct {
        tag=0x12UB,
        name="big",
        value=0x3d31c3f9e3eb9L
    }
}
```

What is the best way? It certainly depends on the kind of data you want to manipulate, and the level of abstraction you want to achieve. Ultimately, it is up to you.

Generally speaking, the best structuring is the one that allows you to manipulate the data in terms of the structured abstractions as naturally as possible. That’s the art and craft of writing good pickles.

### 4.13 Structured Integers

When we structure data using Poke structs, arrays and the like, we often use the same structure than a C programmer would use. For example, to model ELF RELA structures, which are defined in C like:

```c
typedef struct
{
    Elf64_Addr r_offset; /* Address */
    Elf64_Xword r_info; /* Relocation type and symbol index */
    Elf64_Sxword r_addend; /* Addend */
} Elf64_Rela;
```

we could use something like this in Poke:

```c
type Elf64_Rela =
```
Here the Poke struct type is pretty equivalent to the C incarnation. In both cases the fields are always stored in the given order, regardless of endianness or any other consideration.

However, there are situations where stored integral values are to be interpreted as composite data. This is the case of the \texttt{r\_info} field above, which is a 64-bit unsigned integer (\texttt{Elf64\_Xword}) which is itself composed by several fields, depicted here:

\begin{verbatim}
+----------------------+----------------------+
| r\_sym | r\_type |
+----------------------+----------------------+
63 0
\end{verbatim}

In order to support this kind of composition of integers, C programmers usually resort to either bit masking (most often) or to the often obscure and undefined behaviour-prone C bit fields. In the case of ELF, the GNU implementations define a few macros to access these “sub-fields”:

\begin{verbatim}
#define ELF64_R_SYM(i) ((i) >> 32)
#define ELF64_R_TYPE(i) ((i) & 0xffffffff)
#define ELF64_R_INFO(sym,type) ((((Elf64\_Xword) (sym)) << 32) + (type))
\end{verbatim}

Where \texttt{ELF64\_R\_SYM} and \texttt{ELF64\_R\_TYPE} are used to extract the fields from an \texttt{r\_info}, and \texttt{ELF64\_R\_INFO} is used to compose it. This is typical of C data structures.

We could of course mimic the C implementation in Poke:

fun Elf64\_R\_Sym = (Elf64\_Xword i) uint<32>: { return i \textordmasculine} >> 32; }
fun Elf64\_R\_Type = (Elf64\_Xword i) uint<32>: { return i \& 0xffffffff; }
fun Elf64\_R\_Info = (uint<32> sym, uint<32> type) Elf64\_Xword: { return sym as Elf64\_Xword \textordmasculine} << . 32 + type; }

However, this approach has a huge disadvantage: since we are not able to encode the logic of these “sub-fields” in proper Poke fields, they become second class citizens, with all that implies: no constraints on their own, can’t be auto-completed, can’t be assigned individually, \textit{etc}.

But we can use the so-called \textit{integral structs}! These are structs that are defined exactly like your garden variety Poke structs, with a small addition:

\begin{verbatim}
\textbf{type Elf64\_Rel\_Info} =
\textbf{structure uint<64>}
{ 
  uint<32> r\_sym;
  uint<32> r\_type;
};
\end{verbatim}

Note the \texttt{uint<64>} addition after \texttt{struct}. This can be any integer type (signed or unsigned). The fields of an integral struct should be integral themselves (this includes both integers and offsets) and the total size occupied by the fields should be the same size than the one declared in the struct’s integer type. This is checked and enforced by the compiler.

The Elf64 RELA in Poke can then be encoded like:

\begin{verbatim}
\textbf{type Elf64\_Rela} =
\end{verbatim}
struct
{
    Elf64_Addr r_offset;
    struct Elf64_Xword
    {
        uint<32> r_sym;
        uint<32> r_type;
    } r_info;
    Elf64_Sxword r_addend;
};

When an integral struct is mapped from some IO space, the total number of bytes occupied
by the struct is read as a single integer value, and then the values of the fields are extracted
from it. A similar process is using when writing. That is what makes it different with respect a
normal Poke struct.

It is possible to obtain the integral value corresponding to an integral struct using a cast to
an integral type:

(poke) type Foo = struct int<32> { int<16> hi; uint<16> lo; };
(poke) Foo { hi = 1 } as int<32>
0x10000

An useful idiom, that doesn’t require to specify an explicit integral type, is this:

(poke) type Foo = struct int<32> { int<16> hi; uint<16> lo; };
(poke) var x = Foo @ 0#B;
(poke) +x
0xfe00aa

These casts allow to “integrate” struct values explicitly, but the compiler also implicitly
promotes integral struct values to integers in all contexts where an integer is expected:

- Operator to an addition, subtraction, multiplication, division, ceil division, bit left shift, bit
right shift, bit-wise not, bit-wise and, bit-wise or, bit-wise xor, logical and, logical or, logi-
cal not, logical implication, positive, negative, bit-concatenation, condition in conditional
expression.
- Argument to a function whose formal expects an integer.
- Value returned from a function that returns an integer.
- Condition in loop statement.
- Constraint expression in a struct field.
- Expression in a conditional struct field.

Note that the above list doesn’t include relational operators, since these operators work with
struct values.

### 4.14 Working with Incorrect Data

We have seen how Poke type definitions very often include constraint expressions reflecting the
integrity of the data stored in these types.

Consider for example the following abbreviated description of the header of an ELF file:

```plaintext
type Elf64_Ehdr =
struct
{
    struct
    {
        byte[4] ei_mag = [0x7fUB, 'E', 'L', 'F'];
    }
```
There are three constraint expressions in the definition above:

- The constraint expression in the field `ei_mag` makes sure that a right magic number begins the header.
- The constraint expression in `e_version` checks that the ELF version is the current version.
- The constraint expression in `e_shstrndx` checks that the index stored in the field doesn’t overflow the section header table of the file.

Every time we construct or map an `Elf64_Ehdr` value the constraint expressions are checked. In case any of the constraints are not satisfied we get a “constraint violation exception”. This is useful to realize that we are facing invalid data (when mapping) or that we are trying to build an invalid ELF header (when constructing.)

However, the exception avoids the completion of the mapping or construction operation. Sometimes this is inconvenient:

- When we are given invalid data that we want to explore or fix. Imagine for example a programmer investigating a possible assembler or linker bug that results in an invalid ELF file.
- When we are discovering or inferring the structure of some data: we suspect at some point there may be something that is similar to an ELF header.
- When we want to create invalid data. Suppose for example a programmer who is building a test case for the linker, that requires a corrupted ELF file.

The way poke provides support for these situation is using the concept of map strictness. Suppose we map an ELF header in some IO space:

```plaintext
(poke) load elf
(poke) var ehdr = Elf64_Ehdr @ 0#B
```

The mapping operator `@` performs a strict mapping. This means that constraint expressions are evaluated and the operation is interrupted if any constraint fails, as described above. Also, this means the integrity will be checked when the data is modified:

```plaintext
(poke) ehdr.e_version = 666
unhandled constraint violation exception
```

So the mapping operator generates “strict” values. We can check the strictness of a mapped value using the `strict` attribute:

```plaintext
(poke) ehdr.strict
1
```

If we know that we are facing corrupted data, or if we want to corrupt the ELF header, we perform a non-strict mapping using a variant of the mapping operator:

```plaintext
(poke) var ehdr_ns = Elf64_Ehdr @! 0#B
(poke) ehdr_ns.strict
0
```
When mapping is performed in non-strict mode, the constraint expressions are still executed, but their resulting value is discarded. The constraint expressions are executed regardless of strictness because it is fairly common for them to include side-effects that have a calculated impact in subsequent operations, such as for example setting the endianness or some other global state.

We can now corrupt the header in the example above:

```
(poke) ehdr_ns.e_version = 666
```
5 Maps and Map-files

Editing data with GNU poke mainly involves creating mapped values and storing them in Poke variables. However, this may not be that convenient when poking several files simultaneously, and when the complexity of the data increases. poke provides a convenient mechanism for this: maps and map files.

5.1 Editing using Variables

Editing data with GNU poke mainly involves creating mapped values and storing them in Poke variables. For example, if we were interested in altering the fields of the header in an ELF file, we would map an _Elf64_Ehdr_ struct at the beginning of the underlying IO space (the file), like in:

```
(poke) .file foo.o
(poke) load elf
(poke) var ehdr = Elf64_Ehdr @ 0#B
```

At this point the variable _ehdr_ holds an _Elf64_Ehdr_ structure, which is mapped. As such, altering any of the fields of the struct will update the corresponding bytes in _foo.o_. For example:

```
(poke) ehdr.e_entry = 0#B
```

A Poke value has three mapping related attributes: whether it is mapped, the offset at which it is mapped in an IO space, and in which IO space. This information is accessible for both the user and Poke programs using the following attributes:

```
(poke) ehdr'mapped
1
(poke) ehdr'offset
0UL#b
(poke) ehdr'ios
0
```

That’s it, _ehdr_ is mapped at offset zero byte in the IO space 0, which corresponds to _foo.o_:

```
(poke) .info ios
   Id Type Mode Bias Size Name
   * 0 FILE rw 0x00000000#B 0x000004c8#B ./foo.o
```

Now that we have the ELF header, we may use it to get access to the ELF section header table in the file, that we will reference using another variable _shdr_:

```
(poke) var shdr = Elf64_Shdr[ehdr.e_shnum] @ ehdr.e_shoff
(poke) shdr[1]
Elf64_Shdr {
   sh_name=0x1bU#B,
   sh_type=0x1U,
   sh_flags=#<ALLOC,EXEcinstr>,
   sh_addr=0x0UL#B,
   sh_offset=0x40UL#B,
   sh_size=0xbUL#B,
   sh_link=0x0U,
   sh_info=0x0U,
   sh_addralign=0x1UL,
   sh_entsize=0x0UL#b
 }
```

Variables are convenient entities to manipulate in Poke. Let’s suppose that the file has a lot of sections and we want to do some transformation in every section. It is a time consuming
operation, and we may forget which sections we have already processed and which not. We could create an empty array to hold the sections already processed:

(poke) var processed = Elf64_Shdr[] ()

And then, once we have processed some given section, add it to the array:

... edit shdr[23] ...
(poke) processed += [shdr[23]]

Note how the array =processed= is not mapped, but the sections contained in it are mapped: Poke uses copy by shared value. So, after we spend the day carefully poking our ELF file, we can ask poke, are we done with all the sections in the file?

(poke) shdr.length == processed.length
1

Yes, we are. This can be made as sophisticated as desired. We could easily write a function that saves the contents of processed in files, so we can continue hacking tomorrow, for example.

We can then concluding that using mapped variables to edit data structures stored in IO spaces works well in common and simple cases like the above: we make our ways mapping here and there, defining variables to hold data that interests us, and it is easy to remember that the variables ehdr and shdr are mapped, where are they mapped, and that they are mapped in the file foo.o.

However, GNU poke allows to edit more than one IO space simultaneously. Let’s say we now want to poke the sections of another ELF file: bar.o. We would start by opening the file:

(poke) .file bar.o
(poke) .info ios

<table>
<thead>
<tr>
<th>Id</th>
<th>Type</th>
<th>Mode</th>
<th>Bias</th>
<th>Size</th>
<th>Name</th>
</tr>
</thead>
<tbody>
<tr>
<td>* 1</td>
<td>FILE</td>
<td>rw</td>
<td>0x00000000#B</td>
<td>0x00000000#B</td>
<td>./bar.o</td>
</tr>
<tr>
<td>0</td>
<td>FILE</td>
<td>rw</td>
<td>0x00000000#B</td>
<td>0x00000000#B</td>
<td>./foo.o</td>
</tr>
</tbody>
</table>

Now that bar.o is the current IO space, we can map its header. But now, what variable to use? We would rather not redefine ehdr, because that is already holding the header of foo.o. We could adapt our naming schema on the fly:

(poke) var foo_ehdr = ehdr
(poke) var bar_ehdr = Elf64_Ehdr @ 0#B

But then we would need to do the same for the other variables too:

(poke) var foo_shdr = shdr
(poke) var bar_shdr = Elf64_Shdr[bar_ehdr.e_shnum] @ bar_ehdr.e_shoff

However, we can easily see how this can degenerate quickly: what about processed, for example? In general, as the number of IO spaces being edited increases it becomes more and more difficult to manage our mapped variables, which are associated to each IO space.

5.2 poke Maps

As we have seen mapping variables is a very powerful, general and flexible mean to edit stored binary data in one or more IO spaces. However it is easy to lose track of where the variables are mapped and, ideally speaking, we would want to have a mean to refer to, say, the “ELF header”, and get the header as a mapped value regardless of what specific file we are editing. Sort of a “meta variable”. GNU poke provides a way to do this: maps.

A map can be conceived as a sort of “view” that can be applied to a given IO space. Maps have entries, which are values mapped at some given offset, under certain conditions. For example, we have seen an ELF file contains, among other things, a header at the beginning of the file and a table of section headers of certain size and located at certain location determined by the header. These would be two entries of a so-called ELF map.
Poke maps are defined in map files. These files use the .map extension. A map file `self.map` (for sectioned/simple elf) defining the view of an ELF file as a header and a table of section header would look like this:

```plaintext
/* self.map - map file for a simplified view of an ELF file. */

load elf;

%

%entry
  %name ehdr
  %type Elf64_Ehdr
  %offset 0#B

%entry
  %name shdr
  %type Elf64_Shdr[(Elf64_Ehdr @ 0#B).e_shnum]
  %condition (Elf64_Ehdr @ 0#B).e_shnum > 0
  %offset (Elf64_Ehdr @ 0#B).e_shoff
```

This map file defines a view of an ELF file as a header entry `ehdr` and an entry with a table of section headers `shdr`.

The first section of the file, which spans until the separator line containing `%%`, is arbitrary Poke code which as we shall see, gets evaluated before the map entries are processed. This is called the map "prologue". In this case, the prologue contains a comment explaining the purpose of the file, and a single statement `load` that loads the `elf.pk` pickle, since the entries below use definitions like `Elf64_Ehdr` that are defined by that pickle. The prologue is useful to define Poke functions and other entities that are then used in the definitions of the entries.

A separator line containing only `%%` separates the prologue from the next section, which is a list of entries definitions. Each entry definition starts with a line `%entry`, and has the following attributes:

- `%name` Like `ehdr` and `shdr`. These names should follow the same rules than Poke variables, but as we shall see later, map entries are not Poke variables. This attribute is mandatory.
- `%type` This can be any Poke expression denoting a type, like `int`, `Elf64_Ehdr` or `Elf64_Shdr[(Elf64_Ehdr @ 0#B).e_shnum]`. This attribute is mandatory.
- `%condition` If specified, will determine whether to include the entry in the map. In the example above, the map will have an entry `shdr` only if the ELF file has one or more sections. Any Poke expression evaluating to a boolean can be used as conditions. This attribute is optional: entries not having a condition will always be included in the map.
- `%offset` Offset in the IO space where the entry will be mapped. Any Poke expression evaluating to an offset can be used as entry offset. This attribute is mandatory.

### 5.3 Loading Maps

So we have written our `=self.map=`, which denotes a view or structure of ELF files we are interested on, and that resides in the current working directory. How to use it?
The first step is to fire up poke and open some object file. Let’s start with \texttt{foo.o}:

\begin{verbatim}
(poke) .file foo.o
\end{verbatim}

Now, we can load the map using the \texttt{.map load} dot-command:

\begin{verbatim}
(poke) .map load self
\end{verbatim}

The \texttt{.map load self} command makes poke to look in certain directories for a file called \texttt{self.map}, and to load it. The list of directories where poke looks for map files is encoded in the variable \texttt{map_load_path} as a string containing a maybe empty list of directories separated by \texttt{:} characters. Each directory is tried in turn. This variable is initialized with suitable defaults:

\begin{verbatim}
(poke) map_load_path
"/home/jemarch/.poke.d:.:/home/jemarch/.local/share/poke:[...]
\end{verbatim}

Once a map is loaded, observe how the prompt changed to contain a prefix \texttt{[self]}. This means that the map \texttt{self} is loaded for the current IO space. You can choose to not see this information in the prompt by setting the \texttt{prompt-maps} option either at the prompt or in your \texttt{.pokerc}:

\begin{verbatim}
poke) .set prompt-maps no
\end{verbatim}

By default \texttt{prompt-maps} is \texttt{yes}. This prompt aid is intended to provide a cursory look of the "views" or maps loaded for the current IO space. If we load another IO space and switch to it, the prompt changes accordingly:

\begin{verbatim}
(poke) [self](poke) .mem foo
The current IOS is now `*foo*'.
(poke) .ios $<*foo*>
The current IOS is now `./foo.o'.
\end{verbatim}

At any time the \texttt{.info maps} dot-command can be used to obtain a full list of loaded maps, with more information about them:

\begin{verbatim}
(poke) .info maps
IOS Name Source
0 self ./self.map
\end{verbatim}

In this case, there is a map \texttt{self} loaded in the IO space 0, which corresponds to \texttt{foo.o}.

Once we make \texttt{foo.o} our current IO space, we can ask poke to show us the entries corresponding to this map using another dot-command:

\begin{verbatim}
: (poke) .map show self
: Offset Entry
: 0x0UL#B $self::ehdr
: 0x208UL#B $self::shdr
\end{verbatim}

This tells us there are two entries for \texttt{self} in \texttt{foo.o}: $self::ehdr and $self::shdr= Note how map entries use names that start with the \$ character, then contain the name of the map an the name of the entry we defined in the map file, separated by ::. 

We can now use these entries at the prompt like if they were regular mapped variables:

\begin{verbatim}
$self](poke) $self::ehdr
Elf64_Ehdr {
  e_ident=struct {
    ei_magic=[0x7fUB,0x45UB,0x4cUB,0x46UB],
    [...]}
  e_type=0x1UH,
  e_machine=0x3eUH,
\end{verbatim}
It is important to note, however, that map entries like $foo::bar are not part of the Poke language, and are only available when using poke interactively. Poke programs and scripts can’t use them.

Let’s now open another ELF file, and the =self= map in it:

```
(poke) .file /usr/local/lib/libpoke.so.0.0.0
(poke) .map load self
```

So now we have two ELF files loaded in poke: foo.o and libpoke.so.0.0.0, and in both IO spaces we have the self map loaded. We can easily see that the map entries are different depending on the current IO space:

```
Offset Entry
0UL #B $self::ehdr
3158952UL #B $self::shdr
```

foo.o is an object file, whereas libpoke.so.0.0.0 is a DSO:

```
(poke) .ios 0
The current IOS is now `./foo.o'.
```

```
Offset Entry
0UL #B $self::ehdr
520UL #B $self::shdr
```

The interpretation of the map entry $self::ehdr is different depending on the current IO space. This makes it possible to refer to the “ELF header” of the current file.

Underneath, poke implements this by defining mapped variables and “redirecting” the entry names $foo::bar to the right variable depending on the IO space that is currently selected. It hides all that complexity from us.

### 5.4 Multiple Maps

It is perfectly possible (and useful!) to load more than one map in the same IO space. It is very natural for a single file, for example, to contain data that can be interpreted in several ways, or of different nature.

Let’s for example open again an ELF file, this time compiled with -g:

```
(poke) .file foo.o
```

We now load our self map, to get a view of the file as a collection of sections:

```
(poke) .map load self
```
And now we load the dwarf map that comes with poke, to get a view of the file as having debugging information encoded in DWARF:

```
[self(poke)] .map load dwarf
dwarf,self](poke)
```

See how the prompt now reflects the fact that the current IO space contains DWARF info! Let’s take a look:

```
[dwarf,self](poke) .info maps
IOS Name Source
0 dwarf /home/jemarch/gnu/hacks/poke/maps/dwarf.map
0 self ./self.map
[dwarf,self](poke) .map show dwarf
Offset Entry
0x5bUL#B $dwarf::info
```

Now we can access entries from any of the loaded maps, i.e. access the file in terms of different perspectives. As an ELF file:

```
[dwarf,self](poke) $self::shdr[1]
Elf64_Shdr {
  sh_name=0xb5U#B,
  sh_type=0x11U,
  sh_flags=#<>,
  sh_addr=0x0UL#B,
  sh_offset=0x40UL#B,
  sh_size=0x8UL#B,
  sh_link=0x18U,
  sh_info=0xfU,
  sh_addralign=0x4UL,
  sh_entsize=0x4UL#b
}
```

And as a file containing DWARF info:

```
[dwarf,self](poke) $dwarf::info
Dwarf_CU_Header {
  unit_length=#<0x0000004eU#B>,
  version=0x4UH,
  debug_abbrev_offset=#<0x00000000U#B>,
  address_size=0x8UB#B
}
```

If you are curious about how the DWARF entries are defined, look at maps/dwarf.map in the poke source distribution, or in your installed poke (.info maps will tell you the file the map got loaded from.)

It is possible to unload or remove a map from a given IO space using the .map remove dot-command. Say we are done looking at the DWARF in foo.o, and we are no longer interested in it as a file containing debugging info. We can do:

```
[dwarf,self](poke) .map remove dwarf
[self](poke)
```

Note how the prompt was updated accordingly: only self remains as a loaded map on this file.
5.5 Auto-map

Certain maps make sense when editing certain types of data. For example, `dwarf.map` is intended to be used in ELF files. In order to ease using maps, poke provides a feature called `auto mapping`, which is disabled by default.

You can set auto mapping like this:

```
(poke) .set auto-map yes
```

When auto mapping is enabled, poke will look to the value of the pre-defined variable `auto_map`, which must contain an array of pairs of strings, associating a regular expression with a map name.

For example, you may want to initialize `auto_map` like this in your `.pokerc` file:

```
auto_map = [".*\.mp3$", "mp3"],
[".*\.o$", "elf"],
["a\.out$", "elf"];
```

This will make poke to load `=mp3.map=` for every file whose name ends with `.mp3`, and `elf.map` for files having names like `foo.o` and `a.out`.

Following the usual pokeish philosophy of being as less as intrusive by default as possible, the default value of `auto_map` is the empty string.

5.6 Constructing Maps

As we have seen, we can define our own maps using map files like `self.map`, which contain a prologue and a set of map entries. However, sometimes it is useful to create maps “on the fly” while we explore some data with poke.

To make this possible, poke provides a suitable set of dot-commands. Let’s say we are poking some data, and we want to create a map for it. We can do that like this:

```
(poke) .map create mymap
```

This creates an empty map named `mymap`, with no entries:

```
[mymap](poke) .map show mymap
Offset  Entry
```

Adding entries is easy. First, we have to map some variable, and then use it as the base for the new entry:

```
[mymap](poke) var foo = int[3] 0#B
[mymap](poke) .map entry add mymap, foo
[mymap](poke) .map show mymap
Offset  Entry
0x0UL#B $mymap::foo
```

Note how the entry `$mymap::foo` gets created, associated to the current IO space and mapped at the same offset than the variable `foo`.

We can remove entries from existing maps using the `.map entry remove` dot-command:

```
[mymap](poke) .map entry remove mymap, foo
[mymap](poke) .map show mymap
Offset  Entry
[mymap](poke)
```

We plan to add an additional command to save maps to map files. The idea is that you can create your maps on the fly, save them, and then load them back some other day when you are ready to continue poking. This is not implemented yet though.
5.7 Predefined Maps

GNU poke comes with a set of useful pre-written maps, which get installed in a system location. We want to expand this collection, so please send us your map files!
6 Writing Pickles

GNU poke encourages the user to write little pieces of code in order to face spontaneous needs and fix situations. Is that name in the file encoded in a fixed array of characters padded with white spaces? No problem, just write a three lines function so you can update the file using a comfortable NULL-terminated string. Better than waiting for some poke maintainer to add that function for you, isn’t it?

Just save your functions in some personal .pk file that you load at startup, and your magic tricks bag will increase in time, making your poking more and more efficient.

However, when it comes to share the code with other people, it is important to follow certain conventions in order to achieve certain uniformity. This makes it easier for other people to discover what your hack provides, and how it works. It is this consistency, and these conventions, that makes some random .pk file a pickle.

This guide contains guidelines and recommendations for the pickle’s writer.

6.1 Pretty-printers

6.1.1 Convention for pretty-printed Output

Very often the structure of the data encoded in binary is not very intelligible. This is because it is usual for binary formats to be designed with goals in mind other than being readable by humans: compactness, detail etc.

In our pickle we of course want to provide access to the very finer detail of the data structures. However, we also want for the user to be able to peruse the data visually, and only look at the fine detail on demand.

Consider for example an ID3V1 tag data from some MP3 file. This is the result of mapping a ID3V1_Tag:

```plaintext
ID3V1_Tag {
  id=[0x54UB,0x41UB,0x47UB],
  title=[0x30UB,0x31UB,0x20UB,0x2dUB,0x20UB,...],
  artist=[0x4aUB,0x6fUB,0x61UB,0x71UB,0x75UB,...],
  album=[0x4dUB,0x65UB,0x6eUB,0x74UB,0x69UB,...],
  year=[0x20UB,0x20UB,0x20UB,0x20UB],
  data=struct {
    extended=struct {
      comment=[0x20UB,0x20UB,0x20UB,0x20UB,0x20UB,...],
      zero=0x0UB,
      track=0x1UB
    },
    genre=0xffUB
  }
}
```

Not very revealing. Fortunately, poke supports pretty printers. If a struct type has a method called _print, it will be used by poke as a pretty printer if the pretty-print option is set:

```
(poke) .set pretty-print yes
```

By convention, the output of pretty-printers should always start with #< and end with >. The convention makes it explicit for the user that everything she sees between #< and > is pretty-printed, and do not necessarily reflect the physical structure of the data. Also some information may be missing. In order to get an exact and complete description of the data, the user should .set pretty-print no and evaluate the value again at the prompt.
For example, in the following BPF instructions it is obvious at first sight that the shown register values are pretty-printed:

```c
BPFInsn = {
    ...
    regs=BPF_Regs {
        src=#<%r3>,
        dst=#<%r0>
    }
    ...
}
```

If the pretty-printed representation spans for more than one line, please place the opening #< in its own line, then the lines with the data, and finally > in its own line, starting at column 0.

Example of the MP3 tag above, this time pretty-printed:

```xml
<
    genre: 255
    title: 01 - Eclipse De Mar
    artist: Joaquin Sabina
    album: Mentiras Piadosas
    year:
    comment:
    track: 1
>
```

### 6.1.2 Pretty Printing Optional Fields

Let’s say we are writing a pretty-printer method for a struct type that has an optional field. Like for example:

```c
type Packet =
struct
{
    byte magic : magic in [MAGIC1,MAGIC2];
    byte n;
    byte[n] payload;
    if (magic == MAGIC2)
        PacketTrailer trailer;
}
```

In this case, the struct value will have a trailer conditionally, which has to be tackled on the pretty-printer somehow.

An approach that often works good is to replicate the logic in the optional field condition expression, like this:

```c
struct
{
    byte magic : magic in [MAGIC1,MAGIC2];
    [..]
    PacketTrailer trailer if packet_magic2_p (magic);

    method _print = void:
    {
        [..]
        if (magic == MAGIC2)
```
This works well in this simple example. In case the expression is big and complicated, we can avoid rewriting the same expression by encapsulating the logic in a function:

```haskell
fun packet_magic2_p = int: { return magic == MAGIC2; }
type Packet =
struct
  byte magic : magic in [MAGIC1,MAGIC2];
  ...
  if (packet_magic2_p (magic))
    PacketTrailer trailer;

  method _print = void:
  {
    ...
    if (packet_magic2_p (magic))
      pretty_print_trailer;
  }
}
```

However, this may feel weird, as the internal logic of the type somehow leaks its natural boundary into the external function `packet_magic2_p`.

An alternative is to use the following idiom, that checks whether the field actually exists in the struct:

```haskell
type Packet =
struct
  byte magic : magic in [MAGIC1,MAGIC2];
  ...
  if (packet_magic2_p (magic))
    PacketTrailer trailer;

  method _print = void:
  {
    ...
    try pretty_print_trailer;
    catch if E_elem {}
  }
}
```

This approach also works with unions:

```haskell
type ID3V1_Tag =
struct
  { ...
  union
  { /* ID3v1.1 */
    struct
    {
```
Chapter 6: Writing Pickles

```c
char[28] comment;
byte zero = 0;
byte track : track != 0;
} extended;
/* ID3v1 */
char[30] comment;
} data;
[...]

method _print = void:
{
[...]
try print " comment: " + catos (data.comment) + "\n";
catch if E_elem
{
    print " comment: " + catos (data.extended.comment) + "\n";
    printf " track: %u8d", data.extended.track;
}
}
```

### 6.2 Setters and Getters

Given a struct value, the obvious way to access the value of a field is to just refer to it using dot-notation.

For example, for the following struct type:

```c
type ID3V1_Tag =
    struct
    {
    [...] char[30] title;
    char[30] artist;
    char[30] album;
    char[4] year;
    [...]}
```

Suppose the find out the year in the tag is wrong, off by two years: the song was released in 1980, not in 1978! Unfortunately, due to the bizarre way the year is stored in the file (as a sequence of digits encoded in ASCII, non-NULL terminated) we cannot just write:

```c
(poke) tag.year = tag.year + 2
```

Instead, we can use facilities from the standard library and a bit of programming:

```c
(poke) stoca (format ("%d", atoi (catos (tag.year)) + 2), tag.year)
```

The above line basically transforms the data we want to operate on (the tag year) from the stored representation into a more useful representation (from an array of character digits to an integer) then operates with it (adds two) then converts back to the stored representation. Let’s call this “more useful” representation the “preferred representation”.

A well written pickle should provide getter and setter methods for fields in struct types for which the stored representation is not the preferred representation. By convention, getter and setter methods have the following form:

```c
method get_field preferred_type: { ... }
```
method set_field (preferred_type val) void: { ... }

Using the get_ and set_ prefixes consistently is very important, because the pokist using your pickle can easily find out the available methods for some given value using tab-completion in the REPL.

For example, let’s add setter and getter methods for the field year in the ID3V1 tag struct above:

type ID3V1_Tag =
 struct
 { ...
  char[4] year;

  method get_year = int: { return atoi (catos (year)); }  
  method set_year = (int val) void:
   { 
    var str = format ("%d", val);
    stoca (str, year);
   }
  
  [...]
 }

What constitutes the preferred representation of a field is up to the criteria of the pickle writer. For the tag above, I would say the preferred representations for the title, artist, album and year are string for title, artist and album, and an integer for the year.
7 Writing Binary Utilities

GNU poke is, first and foremost, intended to be used as an interactive editor, either directly on
the command line or using a graphical user interface built on it. However, since its conception
poke was intended to also provide a suitable and useful foundation on which other programs,
the so-called binary utilities, could be written. This chapter shows how to write Poke scripts
and programs.

7.1 Poke Scripts

In interactive usage, there are two main ways to execute Poke code: at the interactive prompt
(or REPL), and loading “pickles”.

Executing Poke code at the REPL is as easy as introducing a statement or expression:

(poke) print "Hello\n"
Hello

Executing Poke code in a pickle is performed by loading the file containing the code:

(poke) .load say-hello.pk
Hello

Where say-hello.pk contains simply:

print "Hello\n";

However, we would like to have Poke scripts, i.e. to be able to execute Poke programs as
standalone programs, from the shell. In other words, we want to use GNU poke as an interpreter.
This is achieved by using a shebang, which should appear at the top of the script file. The poke
shebang looks like this:

#!/usr/bin/poke -L
#!

The -L command line option tells poke that it is being used as an interpreter. Additional
arguments for poke can be specified before -L (but not after). The #! ... !# is an alternative
syntax for multi-line comments, which allows to have the shebang at the top of a Poke program
without causing a syntax error. This nice trick has been borrowed from guile.

Therefore, we could write say-hello as a Poke script like this:

#!/usr/bin/poke -L
#!

print "Hello\n";

And then execute it like any other program or script:

$ ./say-hello

7.2 Command-Line Arguments

When a Poke script is executed, the command line arguments passed to the script become
available in the array argv. Example:

#!/usr/bin/poke -L
#!

for (arg in argv)
    print "Argument: " + arg + "\n";

Executing this script results in:

$ ./printargs foo bar 'baz quux'
Argument: foo  
Argument: bar  
Argument: baz quux

Note how it is not needed to have an argc variable, since the number of elements stored in a Poke array can be queried using an attribute: argv\'length.

Note also that argv is only defined when poke runs as an interpreter:

$ poke  
[...]
(poke) argv  
<stdin>:1:1: error: undefined variable \'argv\'
argv;

Accessing the argv is more than enough for many simple programs. However, we may need a more sophisticated handling of command-line options: support for both short and long style options, adherence to the GNU coding standards, and the like. For these cases poke provides a pickle argp. See Section 18.1 [argp], page 110.

7.3 Exiting from Scripts

By default a Poke script will communicate a successful status to the environment, upon exiting:

$ cat hello  
#!/usr/bin/poke -L
!#

print "hello\n";
$ ./hello && echo $?  
0

In order to exit with some other status code, most typically to signal an erroneous situation, the Pokish way is to raise an E_exit exception with the desired exit status code:

raise Exception { code = EC_exit, exit_status = 1 };

This can be a bit cumbersome to write, so poke provides a more conventional syntax in the form of an exit function:

fun exit = (int<32> exit_code = 0) void:
{  
  raise Exception { code = EC_exit, exit_status = exit_code };
}

Using exit, the above raise statement becomes the much simpler:

exit (1);

7.4 Loading pickles as Modules

Suppose we want to write a Poke program to extract the contents of sections in a given ELF object file. Extracting sections requires dealing with several data structures encoded in the ELF file, such as the header, the section header table, the string table (that contains the names of the sections) and so on. It would be of course possible to define Poke types for these structures in the script itself but, as it happens, GNU poke ships with an already written pickle that describes the ELF structures. It is called elf.pk.

So a script needing to mess with ELF data structures can just make use of elf.pk using the load construction:

load elf;
This looks for a file called `elf.pk` in a set of directories, which are predefined by poke, and loads it. The list of directories where poke looks for pickles is stored in the `load_path` variable as a colon separated list of directory names, and can be customized:

```bash
$ poke
[...]
(poke) load_path
"/home/jemarch/.poke.d:.:/home/jemarch/.local/share/poke:..."
```

The default value of `load_path` contains both user-specific directories and system-wide directories. This assures that all the pickles installed by poke are available, and that the user can load her own pickles in her scripts.

Once a pickle is loaded in a script the types, functions and variables defined in it (either directly or indirectly by loading its own pickles) become available.

### 7.5 elfextractor

As an example, in this section we will be hacking a very simple utility called elfextractor, that extracts the contents of the sections of an ELF file, whose name is provided as an argument in the command line, into several output files. This is the synopsis of the program:

```bash
tool elfextractor [section_name]
```

Where `file` is the name of the ELF file from which to extract sections, and an optional `section_name` specifies the name of the section to extract.

Say we have a file `foo.o` and we would like to extract its text section. We would use elfextractor like:

```bash
$ elfextractor foo.o .text
```

Provided `foo.o` indeed has a section named `.text`, the utility will create a file `foo.o.text` with the section’s contents. Note how the names of the output files are derived concatenating the name of the input ELF file and the name of the extracted section.

If no section name is specified, then all sections are extracted. For example:

```bash
$ elfextractor foo.o
$ ls foo.o*
foo.o        foo.o.eh_frame   foo.o.shstrtab   foo.o.symtab
foo.o.comment foo.o.rela.eh_frame foo.o.strtab foo.o.text
```

This is a possible implementation of elfextractor:

```bash
#!/usr/bin/poke -L
#
/* elfextractor - Extract sections from ELF64 files. */

load elf;

if (!((argv.length in [1UL,2UL])))
{
    print "Usage: elfextractor FILE [SECTION_NAME]\n";
    exit (1);
}

var file_name = argv[0];
var section_name = (argv.length > 1) ? argv[1] : "";
```
try {
    var fd = open(file_name, IOS_M_RDONLY);
    var elf = Elf64_File @ fd : 0#B;

    for (shdr in elf.shdr where shdr.sh_type != 0x0) {
        var sname = elf.get_section_name(shdr.sh_name);
        if (section_name == "" || sname == section_name) {
            save :ios elf'ios :file file_name + sname
                 :from shdr.sh_offset :size shdr.sh_size;
        }
    }

    close(fd);
}

catch (Exception e) {
    if (e == E_constraint)
        printf("error: `%s' is not a valid ELF64 file\n", file_name);
    else if (e == E_io)
        printf("error: couldn't open file `%s'\n", file_name);
    else
        raise e;

    exit (1);
}

First the command line arguments are handled. The script checks whether the right number
of arguments have been passed (either 1 or 2) exiting with an error code otherwise. The file
name and the section name are then extracted from the argv array.

Once we have the file name and the optional desired section name, it is time to do the real
work. The code is enclosed in a try-catch block statement, because some of the operations may
result on exceptions being raised.

First, the ELF file whose name is specified in the command line is opened for reading:

    var fd = open(file_name, IOS_M_RDONLY);

The built-in function open returns a file descriptor that can be subsequently used in mapping
operations. If the provided file name doesn’t identify a file, or if the file can’t be read for
whatever reason, an E_io exception is raised. Note how the exception is handled in the catch
block, emitting an appropriate diagnostic message and exiting with an error status.

Once the ELF file is open for reading, we map an Elf64_File on it, at the expected offset
(zero bytes from the beginning of the file):

    var elf = Elf64_File @ fd : 0#B;

If the file doesn’t contain valid ELF data, this map will fail and raise an Econstraint
exception. Again, the catch block handles this situation.

At this point the variable elf contains an Elf64_File. Since we want to extract the sections
contained in the file, we need to somehow iterate on them. The section header table is available
in elf.shdr. A for-in-where loop is used to iterate on all the headers, skipping the “null”
ELF sections which are always empty, and are characterized by a shdr.sh_type of 0. An inner
conditional filters out sections whose name do not match the provided name in the command
line, if it was specified at all.
For each matching section we then save its contents in a file named after the input ELF file, by calling a function \texttt{save}, which is provided by poke:

\begin{verbatim}
  save :ios elf'ios :file file_name + sname
       :from shdr.sh_offset :size shdr.sh_size;
\end{verbatim}

The above is exactly what we would have written at the poke REPL! (modulus trailing semicolon). How is this supposed to work? Thing is, GNU poke commands are implemented as Poke functions. Let’s consider \texttt{save}, for example. It is defined as a function having the following prototype:

\begin{verbatim}
  fun save = (int ios = get_ios,
             string file = "",
             off64 from = 0#B,
             off64 size = 0#B,
             int append = 0,
             int verbose = 0) void:
  {
    ...
  }
\end{verbatim}

Once a Poke function is defined in the environment, it becomes available as such. Therefore, in a poke session we could call it like:

\begin{verbatim}
  (poke) save (get_ios, "filename", 0#B, 12#B, 0, 1)
\end{verbatim}

However, this is cumbersome and error prone. To begin with, we should remember the name, position and nature of each argument accepted by the command. What is even more annoying, we are forced to provide explicit values for them, like in the example above we have to pass the current IOS (the default), and 0 for \texttt{append} (the default) just to being able to set \texttt{verbose}. Too bad.

To ease commanding poke, the Poke language supports an alternative syntax to call functions, in which the function arguments are referred by name, can be given in any order, and can be omitted. The command above can be thus written like:

\begin{verbatim}
  (poke) save :from 0#B :size 12#B :verbose 1
\end{verbatim}

This syntax is mostly intended to be used interactively, but nothing prevents to use it in Poke programs and scripts whenever it is deemed appropriate, like we did in elfextractor. We could of course have used the more conventional syntax:

\begin{verbatim}
  if (section_name == "" || sname == section_name)
    save (elf'ios, file_name + sname,
          shdr.sh_offset, shdr.sh_size, 0, 0);
\end{verbatim}

What style to use is certainly a matter of taste.

Anyhow, once the sections have been written out, the file descriptor is closed and the program exits with the default status, which is success. Should the \texttt{save} function find any problem saving the data, such as a full disk, not enough permissions or the like, exceptions will be raised, caught and maybe handled by our \texttt{catch} block.

And this is it! The complete program is 44 lines long. This is a good example that shows how, given a pickle providing a reasonable description of some binary-oriented format (ELF in this case) poke can be leveraged to achieve a lot in a very concise way, free from the many details involved in the encoding, reading and writing of binary data.

\section{7.6 Filters}

The classic notion of \texttt{filter} in Unix-like systems and other Operating Systems is of a program that reads certain input using its standard input, realized some transformations on it, and writes the result on its standard output. The filter doesn’t need to operate on all the data at once, nor to buffer it: it reads input in chunks once it becomes available and is needed, and write output as necessary.
GNU poke provides the so called stream IO spaces in order to implement binary utilities that act like filters.

### 7.6.1 Stream IO Spaces

GNU poke provides support for opening and operating on several kinds of IO spaces: files, memory buffers, process memory, etc. An IO space can be opened for reading, for writing or both, and they all can be accessed randomly, i.e. to read or write some data from/to a particular offset in the IO space.

Writing a filter would involve to peek data from the standard input and then poke the data (maybe transformed) to the standard output or the standard error output. However, we know that these devices are not random oriented devices that can be accessed at any offset, but rather stream-like devices whose special characteristics are:

- They are either read-only or write-only. You cannot write to an input stream and you cannot read from an output stream.
- Once data is read from an input stream, it can’t be read again. It is not buffered.
- Once data is written to an output stream, it can’t be altered again.

Given the above characteristics of streams like the standard input and output, it is clear we cannot use the File IO streams on them. It is also not clear how could we perform a map operation on a stream device: in poke these operations always require an explicit offset.

GNU poke solves this by providing three special IO spaces that the user can open using the following handlers:

- `<stdin>` Read-only stream IOS that is connected to the standard input of the poke process.
- `<stdout>` Write-only stream IOS that is connected to the standard output of the poke process.
- `<stderr>` Write-only stream IOS that is connected to the standard error of the poke process.

Opening these IO spaces is done exactly like with any other IO space. Example:

```plaintext
var stdin = open("<stdin>");
```

### 7.6.2 Reading from Streams

Unlike normal Unix file descriptors, read-only poke streams are buffered. Let’s supposed we open the standard input:

```plaintext
var stdin = open("<stdin>");
```

Then we map some data (one byte) at some particular offset:

```plaintext
var b = byte @ stdin : 28#B;
```

The mapping operation above causes poke to read 28 bytes from the standard input and to set the variable `b` to the 28-th byte. The bytes read from the stream are still available (buffered) and the offsets are still relative from the “beginning” of the standard input:

```plaintext
var c = byte @stdin : 0#B;
```

The byte in `c` is the byte that appeared in the standard input 27 bytes before the byte in `b`.

This buffering is nice, and it is what allows us to access the standard input like if it were a random oriented device. However, it is obvious we would be in trouble if we filter big amounts of data, like in a network interface: we would likely use all available memory.

To allow filtering big amount of data, poke allows to flush the read-only streams. Flushing means that the buffered data in the read-only stream is “forgotten”, and trying to access it will result in an exception:

```plaintext
var stdin = open("<stdin>");
```
7.6.3 Writing to Streams

Similarly, unlike normal Unix file descriptors, write-only poke streams are also buffered and can be accessed randomly:

```pascal
var stdout = open (<stdout>);
```

We can write to the output stream by mapping as usual:

```pascal
byte @ stdout : 28#B = 0xff;
```

The mapping operation above writes 27 null bytes, i.e. it fills until reaching the requested offset in the output stream. Then it writes the byte 0xff at offset 28 bytes. If we then write to one of the buffered bytes:

```pascal
byte @ stdout : 27#B = 0xab;
```

This results in updating the byte that will be written right before the 0xff once the output stream is flushed.

Again, we cannot buffer ad-infinitum: we would exhaust all available output. Therefore, XXX

7.6.4 pk-strings

Below you can find a very simple Poke program that works like the standard Unix utility strings.

```pascal
#!/usr/local/bin/poke -L
#

/* Printable ASCII characters: 0x20..0x7e */

var stdin = open (<stdin>);
var stdout = open (<stdout>);

var offset = 0#B;

try
{
    flush (stdin, offset);

    var b = byte @ stdin : offset;
    if (b >= 0x20 && b <= 0x7e)
        byte stdout : iosize (stdout) = b;

    offset = offset + 1#B;
}
until E_eof;

close (stdin);
close (stdout);
```
8 .pokerc

Upon invocation poke will read and execute the commands of an initialization file, if it exists: the .pokerc file. There are two ways to keep an initialization file.

The simple, traditional way is to have a file named .pokerc in your home directory. GNU poke will look for a file like that first.

If .pokerc is not found your home directory, poke looks in the locations specified by the XDG Base Directory Specification for a file named poke/pokerc.conf. For example, you could use ~/.config/poke/pokerc.conf.

Which way is better depends on your specific requirements and taste.

GNU poke can be instructed to not read the initialization file by passing -q or --no-init-file in the command line.

Example of initialization file:

```plaintext
# My poke configuration.
.set endian host
.set obase 16
.set pretty-print yes
pk_dump_cluster_by = 4
.load ~/.poke.d/mypickles.pk
```

---

1 https://specifications.freedesktop.org/basedir-spec/basedir-spec-latest.html
9 Load Path

The `load_path` Poke variable contains a list of directories separated by the colon character (`:`). When a module is loaded using the `load` construction, these directories are searched in sequential order for the file corresponding to the requested module.

Empty directory names and entries that do not name existing directories are ignored.

Some entries have special meanings:

%DATADIR%

This is interpreted as the system-wide datadir directory, that depends on the prefix where poke is installed.

For example, say you want to maintain `.pk` files in your `~/.poke.d` directory. You will probably want to add that directory to the `load_path`, when poke initializes. A way to do that is to add a command like this to your `pokerc` file:

```bash
load_path = getenv("HOME") + "/.poke.d:" + load_path
```

If the environment variable `POKE_LOAD_PATH` is defined in the environment, its value is added to `load_path` at poke startup time.
10 Styling

xxx
11 Changing the Prompt

By default the poke command line interface uses a very simple prompt when waiting for commands:

    (poke)  

This prompt never changes.

However, it is possible to customize the prompt by defining a function called `pk_prompt`, that gets no arguments and returns a string. `poke` invokes that function every time it needs to print the prompt; the default version of the function just returns "(poke) ").

This is an example of customization:

```ml
fun pk_prompt = string:
{
    var prompt = "(";

    prompt += get_endian == ENDIAN_BIG ? "big:" : "little:";
    try
        prompt += iohandler (get_ios);
    catch if E_no_ios
        {
            prompt += "poke";
        }

    return prompt + ") ";
}
```

Once the function above gets defined, the prompt will reflect both the current endianness and the currently selected IO space, if there is any:

    (big:poke) .file /bin/ls
    (big:/bin/ls)
12 IOS

The ios pickle contains functions that are useful to work with IO spaces.

12.1 ios_dump_bytes

The ios_dump_bytes function prints a byte dump of an area in a given IO space.

It has the following prototype:

```plaintext
fun ios_dump_bytes = (int<32> ios,
    offset<uint<64>,b> from,
    offset<uint<64>,b> size,
    any val = -1,
    offset<uint<64>, b> group_by = 2#B,
    int<32> cluster_by = 8,
    int<32> ruler = 0,
    int<32> ascii = 0,
    string unknown_byte = "??",
    uint<8> nonprintable_char = '．') void
```

Where ios is the IO space form which dump bytes.

from is the offset from which start dumping bytes. This location is truncated to bytes.

size is an offset specifying the amount of bytes to dump. The offset is rounded up to the
next byte.

val Instead of an explicit from+size range, a mapped value can be specified using the val
argument. In this case, dump will show the bytes corresponding to the given value, with visual
indications on what bytes correspond to what element contained in the value.

group_by determines how the bytes are grouped together in the output. Defaults to two
bytes.

cluster_by specifies to display additioanl space after the specified number of groups have been
displayed. Defaults to 8.

ruler is a boolean determining whether to include a ruler line in the output. Defaults to 0.

ascii_p is a boolean determining whether to include an ASCII dump. Defaults to 0.

unknown_byte is the string to use to denote bytes that can’t be read from the IO space.
Defaults to "??". Note this string is expected to be of length two characters.

nonprintable_char is the character code to use to denote non-printable characters. Defaults
to '．'.

This function may raise E_io, E_perm, and E_eof on several error conditions.

12.2 ios_copy_bytes

The ios_copy_bytes copies a range of bytes between IO spaces.

It has the following prototype:

```plaintext
fun ios_copy_bytes = (int<32> from_ios, int<32> to_ios,
    offset<uint<64>,B> from,
    offset<uint<64>,B> to,
    offset<uint<64>,B> size) void
```

Where from_ios is the origin IO space, i.e. the IO space from which bytes are to be copied.

to_ios is the destination IO space, i.e. the IO space to which bytes are to be copied.

from is a byte offset in from_ios with the beginning of the range to copy.

to is a byte offset in to_ios where the bytes will be copied.

size is a byte offset specifying the amount of data to be copied.
12.3 ios_save_bytes

The function `ios_save_bytes` saves a range of bytes from an IO space to a file.

It has the following prototype:

```plaintext
fun ios_save_bytes = (int<32> ios, string file,
                      offset<uint<64>,B> from,
                      offset<uint<64>,B> size,
                      int<32> append_p) void
```

Where `ios` is the IO space from which save bytes.

`file` is the name of the file where to save the bytes.

`to` and `size` are byte offsets in the IO space determining the range of bytes to save.

By default the output file is truncated if it already exists. If `append_p` is true, then the data is instead appended at the end of the file.
13 Data Encodings

This chapter documents pickles that are related to encoding and decoding data in certain formats such as base64.

13.1 base64

The base64 implements base64 encoding and decoding as described by RFC 4648\(^1\). It provides the following pair of functions:

```haskell
fun base64_encode = (uint<8>[] src) string
fun base64_decode = (string src) uint<8>
```

\(^1\) https://datatracker.ietf.org/doc/html/rfc4648
14 Time

Systems encode time-stamps or dates in several ways. GNU poke provides support for some of them.

14.1 POSIX Time

In POSIX systems time is encoded as a certain number of seconds elapsed since some origin date, namely the first of January 1970. The `time` pickle provides two types for 32-bit and 64-bit POSIX time encodings:

- `POSIX_Time32`
- `POSIX_Time64`

A function `ptime` is also provided, that prints a human-readable representation of a POSIX date, given a number of seconds.
15 Colors

Colors are often found in binary data, encoded in several different ways. GNU poke provides several pickles that makes it easier to work with these colors.

15.1 The Color Registry

The color pickle provides a registry of standard colors, organized as a space of integers. Each integer identifies a standard color, which are accessible as variables named color_* after the pickle is loaded. Example:

```
(poke) load color
(poke) color_tomato
114
```

The purpose of having this register is to have a global namespace for colors that can be used in different pickles. The position of each color in the registry is totally unrelated to how the color may be encoded. Other pickles, as we shall see below, contain tables associating standard colors with their encoding, such as RGB.

If you want to add a new color that is not in the standard collection, you can use the color_register function, which gets no arguments:

```
(poke) var mycolor = color_register
(poke) mycolor
490
```

The total number of registered colors is recorded in the variable color_num_colors. You can use it to iterate on all the colors in the register, from 0 to color_num_colors - 1.

The index in the registry of the first user-defined color is held in the variable color_LAST. For example, if you wanted to store a frob per standard color, you would do it like:

```
(poke) type Frobs = Frob[color_LAST]
```

The pickle also provides a function color_name that, given a color code, returns a printable name for the color, i.e. a string describing it. For user defined colors, this string is fixed:

```
(poke) color_name (23)
"lavender blush"
(poke) color_name (color_register)
"user-defined color"
```

If a non-existent color code is passed to color_name the function raises E_out_of_bounds:

```
(poke) color_name (color_num_colors)
unhandled out of bounds exception
```

15.2 RGB24 Encoding

The RGB24 encoding encodes each color as a triplet of color beans, each beam indicating a level of red, green and blue respectively.

Types are provided for both the color beams, and the triplets:

```
type RGB24_Color_Beam = uint<8>;
type RGB24_Color = RGB24_Color_Beam[3];
```

The indexes RGB24_RED, RGB24_GREEN and RGB24_BLUE can be used to access to a specific beam of a given color:

```
(poke) rgb24_color[color_tomato][RGB24_GREEN]
99UB
```
The rgb24 pickle also provides a table associating poke standard colors (see Section 15.1 [The Color Registry], page 105) with their RGB24 encodings. Once the pickle is loaded, this table is available in the variable rgb24_color. The table is to be indexed by color codes:

(poke) load rgb24
(poke) rgb24_color[color_tomato]
[255UB,99UB,71UB]
16 Audio

16.1 MP3

16.1.1 ID3V1 Tags

The id3v1 pickle provides abstractions in order to edit the metadata stored in a MP3 file.

16.1.1.1 Song Genres

The ID3V1 tags support the notion of song genre. The space for genres is from 0 to 254. The genre code 255 is reserved to mean “no genre”.

The table id3v1_genres can be indexed with a code in order to get the corresponding genre name:

```plaintext
(poke) id3v1_genres[14]
"rhythm and blues"
```

Conversely, the function id3v1_search_genre gives us the code of a genre, given its name. The prototype of this function is:

```plaintext
fun id3v1_search_genre = (string name) uint<8>:
```

For example:

```plaintext
(poke) id3v1_search_genre ("rock") 17UB
```

If id3v1_search_genre is given a name that doesn’t correspond with any genre in the genres table, then E_inval is raised.

16.1.1.2 The ID3V1_Tag Type

The main data structure defined in the id3v1 pickle is ID3V1_Tag, which corresponds to a ID3V1 tag (surprise!). Tags comprise the following information:

− The title of the song, which is limited to 30 bytes.
− The artist, which is limited to 30 bytes.
− The album, which is limited to 30 bytes.
− The year, which is encoded as text in 4 bytes, each byte containing the ASCII code for the corresponding digit.
− A comment, which is limited to either 28 or 30 bytes, depending whether the tag contains track information or not.
− An optional track, which is an unsigned 8-bit number.

The specification does not mention any specific encoding for the entries that store text (such as title or artist), but it is safe to assume some ASCII-compatible encoding is used.

The text entries are stored as arrays of characters, and they are not finished by NULL characters. Instead the arrays of characters are filled with whitespaces (ASCII code 0x20) at the right. For example, the artist name Picasso encoded in ID3V1 would be:

```plaintext
```

In order to ease the manipulation of the text fields, setters and getters are provided in order to handle these values as strings and not as whitespace-filled arrays of characters. Example:

```plaintext
(poke) tag.title [48UB, 49UB, 32UB, 45UB, 32UB, ...]
(poke) tag.get_title
```
"01 - Eclipse De Mar"

Also for setters:

(poke) tag.set_title ("Join us Now")
(poke) tag.title
[74UB,111UB,105UB,110UB,32UB,...]

Setters and getters are also provided in order to manipulate the year as an integer value:

(poke) tag.year
[0x31UB,0x39UB,0x38UB,0x30UB]
(poke) tag.get_year
1980
(poke) tag.set_year (1988)
17 Object Formats

This chapter is of special interest to toolchain developers, people doing reverse-engineering, and similar low-level development activities.

17.1 ELF

poke-elf (https://jemarch.net/poke-elf) is a full-fledged pickle for editing ELF object files, executables, shared libraries and core dumps. It supports many architectures and extensions.

17.2 Dwarf

XXX
18 Programs

This chapter describes pickles whose purpose is to facilitate the writing of binary utilities in Poke.

18.1 argp

Like any other program, Poke scripts often need to handle options passed in the command line. The argp pickle provides a convenient and easy way to handle these arguments.

The main entry point of the pickle is the function argp_parse, with the following prototype:

```plaintext
fun argp_parse = (string program,
                  string version = "",
                  string summary = "",
                  Argp_Option[] opts = Argp_Option[](),
                  string[] argv = string[](),
                  int allow_unknown = 0) string[]
```

Where `program` is the name of the program providing the command-line options. `version` is either a string identifying the version of the program, or the empty string. `summary` is a short summary of what the program does. `opts` is an array of `Argp_Option` structs, each of which describe a command line option and, in particular, a handler for that option. `argv` is an array of string containing the command line elements to process. Finally, `allow_unknown` specifies whether unknown options constitute an error or not. This last option is useful in order to support sub-parsers.

Once invoked, `argp_parse` analyzes the command line provided in `argv`, recognizes options, performs checks making sure that all specified options are well formed, and that every option requiring an argument gets one, invokes the handlers registered for each option, and finally returns an array of non-option arguments in `argv`, for further processing by the user.

Each `Argp_Option` struct describes an option. They have this form:

```plaintext
type Argp_Option =
  struct
    string name;
    string long_name;
    string summary;
    string arg_name;
    int arg_required;
    Argp_Option_Handler handler;
  end;
```

Where `name` is a string of size one character specifying the short name for the option. `long_name` is a non-empty string of any size specifying the long name for the option. `summary` is a short paragraph with a summary of that the option does. `arg_name`, if specified, is a string to be used to describe the argument of the option in the --help output. If `arg_name` is not specified then "ARG" is used. `arg_required` is a boolean specifying whether the option accepts and expects an argument. Defaults to 0. Finally, `handler` is a function that will be invoked to process the option. The function has the following prototype:

```plaintext
type Argp_Option_Handler = (string)void
```

The `argp_parse` function provides default handlers for several standard options:

--help The default handler for this option prints out an usage message in the standard GNU way, and exits. In particular, this output is compatible with the `help2man` utility.
--version

The default handler for this option prints out the name and the version of the program, and exits.

If the user provides handlers for the options above, these take precedence wrt the default handlers.

Several short options can be accumulated this way:

```
foo -qyz
```

The special option `--`, if found in the command line, stops the processing of options. Everything found about it is considered non-option arguments.
19 poked

The poke application is a REPL (Read-Evaluate-Print-Loop) and therefore the user interacts with it by providing Poke statements or expressions (or dot-commands) in the standard input, and then the program prints the response to the commands in the standard output, or standard error. This is good for human users, but not that convenient for other programs that may wish to communicate with a poke incremental compiler.

poked is a different sort of application that accepts Poke code (and more) over Unix sockets and provides responses over the same socket. This is very convenient for programs to interact with the poke incremental compiler. The client programs that interact with poked are called pokelets.

This form of interaction is particularly useful to write user interfaces to GNU poke, in the form of several pokelets. Examples of such interfaces are Emacs interface to poke (https://git.savannah.gnu.org/cgit/poke/poke-el.git) and pacme (https://sourceware.org/pacme/).

poked is basically a message broker that provides (for now) 120 input channels and 120 output channels. The first 60 channels are reserved for the poked developers in order to provide standard channels whose meaning is fixed and the same for any pokelet. The rest of the channels can be freely dedicated for any purpose by anybody else.

The combination of channel number and channel direction creates the client’s role. For now, it’s a single byte. The most significant bit determines whether it’s an input or output channel.

Or in poke syntax:

```c
var PDAP_DIRECTION_IN = 0 as uint<1>,
    PDAP_DIRECTION_OUT = 1 as uint<1>;

type PDAP_Role = struct uint<8>
{
    uint<1> direction;
    uint<7> channel : 0 < channel && channel <= 120;
};
```

Pokelets are expected to write their role over the socket when they’re connected to the poked. poked, on start up, will create a Unix socket and prints current options to the stdout. Options are a pair of space-separated key/values, each on one line. Options will end with an empty line. An example of poked output:

```
socket_path /tmp/poked.ipc
pdap_version 0
```

Currently, only first two input channels are active. Input channel number 1 is for code input which means anything sent to this channel will be compiled and executed using pk_compile_buffer function of libpoke; and input channel number 2 is for command input which will compile and execute the input message using pk_compile_statement function.

For output channels:

Channel 1  Terminal output.
Channel 2  View (vu) output.
Channel 3  Poke Virtual Machine (PVM) disassembly output.
Channel 4  Treevu (tree view) output (not supported yet).
Channel 5  Auto-completion output.
Chapter 19: poked

Channel 6  CPU disassembly output.

The following functions are available for pokelets:

poked_pdap_version
   Version of current PDAP (PokeD Application Protocol).

poked_libpoke_version
   Version of libpoke.

poked_restart
    Restart the Poke environment of poked.

poked_exit
    Exit the poked.

poked_chan_send
    Signature: (uint<7> chan, byte[] data) void. Send data to the specified output
    channel.

    The following variable is also available for pokelets to use:

poked_after_cmd_hook
    An array of callbacks to be run after executing the command (received from input
    channel 2). Callback signature: ()void.
20 pokefmt

pokefmt is a template system to embed Poke code in files. It copies the content from standard input to standard output and replaces the Poke code with the result of execution. You can write Poke code between \{ and \} delimiters. To simplify printing of expressions, pokefmt also supports embedding of Poke expressions between %{ and %} delimiters.

As an example, pokefmt will transform the following text
\[
\%
\begin{align*}
\text{load riscv;} \\
\text{var } a = 1, b = 2;
\end{align*}
\%
\]
The encoding of ADD R3, R2, R1 instruction in RISC-V instruction set is \%(printf "0x%u32x", rv32_add (3, 2, 1);)%.

The result of \%(a)% + \%(b)% is \%(a + b)%.

to this text:

The encoding of ADD R3, R2, R1 instruction in RISC-V instruction set is 0x001101b3.

The result of 1 + 2 is 3.

You can customize the printer for expressions by re-defining pokefmt_expr_printer function. For example,
\[
#as: -march=rv32i \\
#objdump: -dr
\%
\begin{align*}
\text{load riscv;}

21 Programming Emacs Modes

GNU poke ships with a bunch of Emacs major modes that eases writing Poke and PVM assembly. This chapter documents these modes.

21.1 poke-mode

poke-mode is a major mode for editing Poke source files, i.e. .pk files. It provides font-lock, auto-completion and indentation features.

poke-mode is no longer part of the poke source, it is available from GNU ELPA instead and can be installed via M-x package-install ret poke-mode. You can automatically load poke-mode by adding it to auto-mode-alist:

(add-to-list 'auto-mode-alist '("\.pk\" . poke-mode))

21.2 poke-map-mode

poke-map-mode is a major mode for editing poke map-files. It provides font-lock. See Chapter 5 [Maps and Map-files], page 77.

21.3 poke-ras-mode

poke-ras-mode is a major mode for editing PVM assembly. It is used in the development of GNU poke. See the file libpoke/ras in the source distribution for more information about RAS, our Retarded Assembler.
22 Vim Syntax Highlighting

GNU poke ships with a vim syntax highlighter for *.pk files. Normally this should be installed as part of your existing poke installation and work out of the box. If that is not the case this chapter explains how to install it manually.

22.1 poke.vim

etc/vim/syntax/poke.vim is a syntax highlighter for Poke source i.e. *.pk files. To use it, first place the file in your ~/.vimrc/syntax/ folder on Unix based systems, or in $HOME/vimfiles/syntax/ on Windows. There are a few ways to tell Vim to use poke.vim for .pk files, but the quickest is to add the following line to your .vimrc:

    au BufRead,BufNewFile *.pk set filetype=poke
23 Dot-Commands

23.1 .load
The .load command loads a file containing Poke code and compiles and executes it. These files usually have the extension .pk.

If a relative path is provided, then prefix/share/poke is tried first as a base directory to find the specified file. If it is not found, then the current directory is tried next.

If the environment variable POKEDATADIR is defined, it replaces prefix/share/poke. This is mainly intended to test a poke program before it gets installed in its final location.

If an absolute path is provided, it is used as-is.

23.2 .source
The .source command executes command lines from some given file. The syntax is:

```
.sourcopath
```

where path is a path to the file containing the commands. See Section 1.4.4 [Command Files], page 8.

23.3 .file
The .file command opens a new IO space backed by a file, or switches to a previously opened file. When reading or writing the file is accessed via the read and write syscalls. An alternative using the mmap syscall is implemented as .mmap command. See Section 23.3 [file command], page 118, The syntax is:

```
.filepath
```

where path is a path to a file to open, which can be relative to poke's current working directory or absolute.

Tilde expansion is performed in path, much like it's done in the shell. This means you can include special characters like ~ (which will expand to your home directory) delimit the file name with " in case it includes leading or trailing blank characters, etc.

When a new file is opened it becomes the current IO space. From that point on, every map executed in the REPL or while loading a Poke program will operate on that IO space:

```
(poke) .file foo.o
The current file is now 'foo.o'.
```

When .file opens a file, it is opened in whatever mode makes more sense: if the file allows to be written and read then the IO space is open in read/write mode, for example.

If the specified file path doesn’t exist then poke emits an error. However, the flag /c (for “create”) can be passed to the command to tell poke it should create a new file.

23.4 .mem
The .mem command opens a new IO space backed by a memory buffer. The syntax is:

```
.memname
```

where name is the name of the buffer to create. Note that poke adds prefix and trailing asterisk characters, to differentiate file names from buffer names.

When invoked with no name, poke generates a new unique name for the buffer.

When a new memory buffer IOS is opened it becomes the current IO space. See Section 23.3 [file command], page 118.
Chapter 23: Dot-Commands

23.5 .mmap

The .mmap command opens a new IO space where the content is memory mapped from the device driver or file system. This is especially useful when a kernel driver offers a mmap function for mapping the content of kernel memory into userspace. The most famous example is the mem device with its device node /dev/mem. But there are also many drivers especially in embedded systems using it.

In the case of a regular file the mapping is done by the file system driver. For regular files the .file command would be an alternative and should deliver the same result. The difference is that .file is using read and write system calls to retrieve or set the content of the file whereas .mmap is using the mmap system call which is copying the data from the file into ram memory. This is done by the file system driver and on nowadays file systems .file and .mmap are offered by them. When having enough free ram and accessing the file very often the .mmap is supposed to be faster because there are less system calls to be executed. See Section 23.3 [file command], page 118.

In the case of a device driver the behavior depends on the implementation of the driver. It particularly depends on the offered read, write and mmap functions. With /dev/mem for example .file and .mmap should deliver the same results. But there are many drivers used in embedded systems especially for customer hardware which are offering either read and write or mmap. In such a case only the corresponding command can be used. For example when dealing with large amounts of data (video stream) which should be visible to the userspace for further processing it’s almost impossible to copy every single picture to userspace with a driver read function. In such cases device drivers often only offer a mmap function which avoids the extra copying operation.

The syntax is:

```
mmap filename, base, size
```

where `filename` is the name of the device node or the file name, `base` is the starting offset (or base address) of the mapping and `size` is the length of the mapped area.

The `base` has to be a multiple of the MMU page size on the system. It can be retrieved via the C function getpagesize(). On most systems it’s 4096 Bytes.

The following example is mapping the GPIO registers via /dev/mem on the Beaglebone black board and reading the output enable (GPIO_OE) and data out (GPIO_DATAOUT) registers of the IO memory:

```
$ poke
(poke) .mmap /dev/mem, 0x4804c000, 0x1000
(poke) int 0x13C#B
(poke) int 0x134#B
```

When using int on 32 bit systems the full address bus width is used when reading and the same applies to 64 bit systems with the long datatype. All accesses with less bytes than the address bus width are done via a byte by byte copy.

Please write to the poke-devel mailing list if you need a different alignment.

Warning: One should be aware that when writing to mapped registers one is writing to the hardware. Therefore one should be aware of the meaning of the registers as well as the electrical circuit connected. Otherwise the hardware can easily be destroyed. To give an example this could happen when setting a GPIO as output with a high signal while in fact it is connected as an input on the electrical circuit with low signal.

23.6 .nbd

The .nbd command opens a new IO space backed by an external NBD server. The syntax is:

```
nbd uri
```
where uri is the name of the newly created buffer, matching the NBD URI specification (https://github.com/NetworkBlockDevice/nbd/blob/master/doc/uri.md).

When a new NBD IOS is opened, it becomes the current IO space. See Section 23.3 [file command], page 118.

NBD support in GNU poke is optional, depending on whether poke was compiled against libnbd.

For an example of connecting to the guest-visible content of a qcow2 image, with the default export name as exposed by using qemu as an NBD server:

$ qemu-nbd --socket=/tmp/mysock -f qcow2 image.qcow2
$ poke
(poke) .nbd nbd+unix:///socket=?/tmp/mysock
The current file is now `nbd+unix:///socket=?/tmp/mysock'.

23.7  .proc
The .proc command opens a new IO space backed by the memory mapped for some live process, or switches to a previously opened process. The syntax is:

    .proc pid

where pid is a process identifier. In most systems this is a number.

23.8  .sub
The .sub command opens a new IO sub-space. The syntax is:

    .sub ios, base, size[, name]

where ios identifies some existing IO space, base and size are integers denoting the base and size of the range covered by the sub-space (in bytes) and name is an optional name.

23.9  .ios
A list of open IO spaces, and their corresponding identifiers and names, can be obtained using the .info ios command. You can use the .ios command to switch back to a particular IO space by providing an expression that evaluates to its identifier:

    (poke) .ios 1
    The current IOS is now `foo.o'.
    (poke) .ios $</bin/ls>
    The current IOS is now `/bin/ls'.

23.10 .close
The .close command closes the selected IO space. The syntax is:

    .close ios

Where ios is a Poke expression that evaluates to an IO space identifier. Examples:

    (poke) .close 1
    (poke) .close $<*foo*>

Note that closing an IO space with this dot-command implies closing any sub IO space having it as a base.
23.11 .doc

The .doc command is used to display this manual in poke's REPL. The syntax is:

```
.doc [node]
```

where node is an optional parameter which indicates the chapter or section at which the manual should be opened.

This command uses whatever documentation viewer configured using .set doc-viewer whose valid options are either info and less.

Unless doc-viewer is set to less, this command uses the info program (The GNU Texinfo Manual) to interactively present the manual. If info is not installed, then less is tried next.

When using less to display the documentation, the entry in the Table of Contents corresponding to the requested entry is highlighted. Just press / and then RET to jump to the corresponding section in the manual.

If neither info nor less are installed, the .doc command will fail. If poke is not running interactively then .doc does nothing.

23.12 .editor

The .editor command (usually abbreviated as .edit) invokes an external text editor on a temporary file. You can then put contents on that file, save it and exit the editor. At that point poke will read the file contents, turn them into a single line and execute them in the repl. If poke is not running interactively, then .editor does nothing.

The editor used is identified by the EDITOR environment variable.

23.13 .info

The .info command provides information about several kinds of entities. The recognized sub commands are:

```
.info ios
```

```
(poke) .info ios
   Id  Type  Mode   Bias   Name
   1     FILE r 0x00000000B 0x0000df78B  foo.o
 * 0     FILE rw 0x00000000B 0x00000022B  foo.bson
```

The file acting as the current IO space is marked with an asterisk character * at the beginning of the file. The mode in which the file is open is also specified. The Id field is the tag of the file that can be passed to the .file command in order to switch to it as the new current IO space:

```
(poke) .ios 1
The current file is now 'foo.o'.
(poke) .info ios
   Id  Type  Mode   Bias   Name
 * 1     FILE r 0x00000000B 0x0000df78B  foo.o
  0     FILE rw 0x00000000B 0x00000022B  foo.bson
```

```
.info variables [regexp]
```

Shows a list of defined variables along with their current values and the location where the variables were defined. If a regular expression is provided then only the types whose name match the expression are listed. If a regular expression is provided then only the types whose name match the expression are listed.
.info functions [regexp]
Shows a list of defined functions along with their prototypes and the location where
the functions were defined. If a regular expression is provided then only the types
whose name match the expression are listed. If a regular expression is provided then
only the types whose name match the expression are listed.

.info types [regexp]
Shows a list of defined types along with the locations where the types were de-
defined. If a regular expression is provided then only the types whose name match the
expression are listed.

.info type expr|type_specifier
Prints a description of the type of the expression expr, or of the type with specifier
with name type_specifier.

23.14 .set
The .set command allows you to inspect and set the value of global settings. The following
invocations are valid:

.set
Prints all settings along with their values.

.set setting
Prints the value of the given setting.

.set setting value
Sets the value of setting to value.

The following settings can be handled with .set:

pretty-print
This setting determines whether poke should use pretty-printers while printing out
the written representation of struct values.
Pretty-printers are defined as methods named \`print\'.

auto-map
This setting determines whether to automatically load map files when opening IO
spaces.
The decision of what maps to load is driven by the contents of the array \`auto_map\'.
Each entry in the array is an array whose first element is a regular expression, and
the second element is the name of a map.
Example:
auto_map = [[\".o\", \"elf\"], [\".o\", \"dwarf\"]];
The entry above makes poke to automatically load the maps \`elf.map\' and
\`dwarf.map\' when opening any file whose name ends in \`.o\', provided \`auto-map\' is
set to \`yes\'.

prompt-maps
This setting determines whether a list of open maps is displayed before the poke
prompt.
Example of a prompt with map information and \`prompt-maps\' set to \`yes\':
(poke) .file foo.o [dwarf,elf](poke)
Which indicates that the opening of the IO space \`foo.o\' resulted in the \`elf.map\'
and \`dwarf.map\' maps to be automatically loaded.

omap
This sort of misnamed setting determines whether to show the mapped offsets and
element/field offsets of composite values like arrays and structs.
Example:
(poke) .set omaps yes (poke) [1,2,3] [0x1 @ 0x0UL#b,0x2 @ 0x20UL#b,0x3 @ 0x40UL#b] @ 0x0UL#b

This setting defaults to ‘no’.

**obase**
This setting determines the output numerical base to use when printing integral values like integers, offset magnitudes, and the like. The supported bases are 2 for binary, 8 for octal, 10 for decimal and 16 for hexadecimal.

**oacutoff**
This setting determines the maximum number of elements to output when printing out array values. Once the maximum number of elements is reached, an ellipsis ‘...’ is printed to represent the rest of the elements.

Example:
(poke) [1,2,3,4,5] [1,2,3,4,5] (poke) .set oacutoff 3 [1,2,3,...]
The default value is 0, which means no limit.

**odepth**
This setting determines the maximum number of nested structs to output when printing struct and union values. Once the maximum number of nested values is reached, a collapsed form ‘Type {...}’ is printed.

Example:
(poke) type Foo = struct { struct { int i; } bar; } (poke) Foo {} Foo { bar=struct {...} }
The default value for ‘odepth’ is 0, which means infinite depth.

**oindent**
This setting determines the width (in blank characters) of each indentation level when printing out struct values in ‘tree’ mode.

Example:
(poke) .set oindent 4 (poke) Foo {} Foo { i=0x0, l=0x0L }
This setting defaults to 2. See also "help omode".

**omode**
This setting determines the way binary struct data is displayed.

In ‘flat’ mode data is not formatted in any special way. Each value, be it simple or composite, is printed on one line.

In ‘tree’ mode composite values like structs and arrays are displayed in an hierarchical way, using newlines and indentation.

Examples:
(poke) .set omode flat (poke) Foo {} Foo {i=0x0,l=0x0L}
(poke) .set omode tree (poke) Foo {} Foo {i=0x0,l=0x0L}
The default value of ‘omode’ is ‘flat’.

**endian**
This setting determines the byte endianness used when accessing IO spaces. Valid values are ‘big’, ‘little’, ‘host’ and ‘network’.

The meaning of ‘big’ and ‘little’ is the obvious one: the endianness is set to big-endian and little-endian respectively.

The ‘host’ endianness is the endianness used by the computer and operating system that is running poke in order to handle its own memory and files.

The ‘network’ endianness is the endianness used by the host machine in order to communicate with the network.

**doc-viewer**
This setting determines what mechanism to use to open the online user manual.
If ‘info’ is selected, the GNU info standalone program is launched to show the info version of the user manual.

If ‘less’ is selected, the less utility is launched to show a plain text version of the user manual.

See also ".help .doc".

**pager**

This setting determines whether the output of poke commands will be paged or not. Each page will have the height of the terminal.

This setting is ‘no’ by default.

**tracer**

This setting determines whether the Poke compiler and runtime will generate tracing events or not. This is mainly useful for debugging purposes.

Beware that enabling tracer will undoubtedly have an impact in performance, and that every type compiled when tracing is enabled will contain instrumentalization. This means you will most likely want to re-compile the types with tracing disabled once the debugging is done.

This setting is ‘no’ by default.

**autoremap**

This setting determines whether poke will remap mapped values automatically when they are referred to. This assures that the values are always up to date with respect the contents of the IO space.

Turning auto-remap off may be useful in situations where it is very slow to keep all the data structures up to date. In these case, you can ‘.set autoremap off’ and then use the ‘remap’ Poke operator to force the re-mapping of any given value, explicitly.

This setting is ‘yes’ by default.

### 23.15 .vm

The Poke Virtual Machine (PVM) executes the programs that are the result of the compilation of what you write in the REPL or the pickles you load. The .vm command provides sub-commands to interact with the PVM.

#### 23.15.1 .vm disassemble

The .vm disassemble command provides access to the PVM disassembler. It supports the following subcommands:

**.vm disassemble expression expr**

Dumps the assembler corresponding to the Poke expression expr.

**.vm disassemble function function**

Dumps the assembler corresponding to the Poke function called function. The function shall be reachable from the top-level.

**.vm disassemble mapper expr**

If expr is a mapped value, dumps the assembler corresponding to its mapper function.

**.vm disassemble writer expr**

If expr is a mapped value, dumps the assembler corresponding to its writer function.

The disassembler will provide a PVM disassembly by default, but it can be passed the flag /n to do a native disassembly instead in whatever architecture running poke.
23.15.2 .vm profile
The .vm profile command provides access to the PVM profiler. This profiler is only available if poke has been configured with PVM profiling support. This command supports the following subcommands:

.vm profile reset
  Resets the profiling counts in the virtual machine.

.vm profile show
  Outputs a summary with both counts and sample information.

23.15.3 .vm dispatch
The .vm dispatch command prints the current dispatching strategy in PVM (provided by Jitter). There are four different kinds of dispatches:

- switch
- direct threading
- minimal threading
- no threading

no threading is the fastest one and the least portable dispatch, and switch is the slowest and the most portable one.

Jitter by default will use the most efficient dispatch which is both stable and available for the current configuration.

23.16 .compiler
The .compiler family of dot-commands provide access to auxiliary features of the Poke incremental compiler. This is mostly used for debugging poke itself.

23.16.1 .compiler ast
The .compiler ast command compiles a Poke expression and then dumps a printable representation of the corresponding abstract syntax tree (AST). This command is useful when debugging the Poke compiler.

23.17 .exit
The .exit command exits poke. The syntax is:

.exit [status]

Poke will terminate, returning the exit status status. If status is omitted, then the exit status zero will be returned.

23.18 .quit
The .quit command behaves exactly like .exit. See Section 23.17 [exit command], page 125.
24 Commands

24.1 dump

At the most basic level, memory can be examined byte by byte. To do this, use the dump command.

This command has the following synopsis.

```
dump [:from offset] [:size offset] [:val val]
[:ios int] [:ruler bool]
[:ascii bool] [:group_by int] [:cluster_by int]
```

All arguments are optional, which means the simplest use of the command is to simply type dump:

```
(poke) dump
76543210 0011 2233 4455 6677 8899 aabb cccd deeff 0123456789ABCDEF
00000000: 9b07 5a61 4783 f306 4897 f37c fe39 4cd3 ..ZaG...H..|.9L.
00000010: 31df 8ecb 3d33 ee12 429b 2e13 67d9 948e 1...=3..B..g...
00000020: 86f1 2228 ae07 d95c 9884 cf0a d1a8 072e .."(........
00000030: f93c 5368 9617 6c96 3d61 7b92 9038 a93b .<Sh..l.=a{.8.;
00000040: 3b0d f8c9 efbd a959 88d0 e523 fd3b b029 ;......Y...#
00000050: e2eb 51d5 cb5b 5ba9 b890 974a 2746 72ad 1...Q[...z'Fr.
00000060: 6cbd 6e27 1c7f a554 8d2e 7f9f 315a 4415 l.n'...T..w.1ZD.
```

The first row is the ruler which serves as a heading for each subsequent row. On the left hand side is the offset of the io space under examination. The centre block displays the hexadecimal representation of each byte, and on the right hand side is their ascii representation. If a byte is not representable in ascii, then the byte will be displayed as a dot.

By default the dump command reads from the currently selected IO space. However, it is possible to specify an explicit IO space using the ios option:

```
(poke) var myfile = open ("/path/to/file")
(poke) dump :ios myfile
```

24.1.1 Information dump shows

By default dump displays 128 bytes of memory starting at offset 0#B. You can change the quantity and starting offset by using the size and from arguments. For example:

```
(poke) dump :from 0x10#B :size 0x40#B
76543210 0011 2233 4455 6677 8899 aabb cccd deeff 0123456789ABCDEF
00000010: b6a2 a578 8d82 7b7f 2076 374c 3eab 7150 ...x..{. v7L>.qP
00000020: 31df 8ecb 3d33 ee12 429b 2e13 67d9 948e 1...=3..B..g...
00000030: 86f1 2228 ae07 d95c 9884 cf0a d1a8 072e .."(........
00000040: f93c 5368 9617 6c96 3d61 7b92 9038 a93b .<Sh..l.=a{.8.;
00000050: 3b0d f8c9 efbd a959 88d0 e523 fd3b b029 ;......Y...#
00000060: e2eb 51d5 cb5b 5ba9 b890 974a 2746 72ad 1...Q[...z'Fr.
00000070: 6cbd 6e27 1c7f a554 8d2e 7f9f 315a 4415 l.n'...T..w.1ZD.
```

Note that both the size and from arguments are offsets. As such, both must be specified using # and an appropriate unit. (see Section 25.3.1 [Offset Literals], page 135).

The other arguments change the appearance of the dump. If the ruler argument is zero, then the ruler will be omitted:

```
(poke) dump :ruler 0 :size 0x40#B
00000000: b1fd 1608 2346 759c 46a6 aa94 6fcd 846a ....#Fu.F...o..j
00000010: e3f3 473f 3247 141f 174d a32b ed89 a435 ..G72A_.M.+...5
00000020: d2c6 2c52 bc82 e0a7 e767 31ea 84de 41e5 ...R...g1...A.
00000030: 2add 2869 e9c2 226b e222 8c74 4b94 af24 *.i."k.".tK...
```
To omit the ascii representation of the memory, call `dump` with the `ascii` argument set to zero:

```
(poke) dump :ruler 0 :size 0x40#B :ascii 0
```

```
00000000: 4393 85e7 0b0c 3921 5a26 39ec 2f5f 5f15
00000010: cc46 e6f3 d50f 6ae6 8988 d50e f8c4 1c6
00000020: 5a2f 7c3e 490b 18d8 d867 4b6f 2549 1f6c
00000030: 3a99 a0d7 24d2 e9ac 9240 8247 10cb 4b1a
```

Instead of an explicit `from+size` range, a mapped value can be specified using the `val` argument. In this case, `dump` will show the bytes corresponding to the given value, with visual indications on what bytes correspond to what element contained in the value.

Let’s first see an example with a struct:

```
(poke) type Foo = struct { int<32> one; int<64> two; }
(poke) dump :val Foo @ 0#B
```

```
76543210 0011 2233 4455 6677 8899 aabb ccdd eeff 0123456789ABCDEF
00000000: 0000 0000 0000 0000 0000 0000 ............ one two
```

Where both the bytes and the field names are colorized in order to establish a visual correspondence.

Similarly, the bytes corresponding to array elements are also characterized:

```
(poke) dump :val int[3] @ 0#B
```

```
76543210 0011 2233 4455 6677 8899 aabb ccdd eeff 0123456789ABCDEF
00000000: 0000 0000 0000 0000 0000 0000 ............ [0] [1] [2]
```

If some of the elements contained in the value passed to `dump` is itself complex, then a number is printed right before its name. For example:

```
(poke) type Foo = struct { int<32> one; struct { int<64> three; } two; }
(poke) dump :val Foo @ 0#B
```

```
76543210 0011 2233 4455 6677 8899 aabb ccdd eeff 0123456789ABCDEF
00000000: 0000 0000 0000 0000 0000 0000 ............ one one=two
```

This number can be used as an identifier in a subsequent invocation to `dump` to quickly refer to that value:

```
(poke) dump :val 1
```

```
76543210 0011 2233 4455 6677 8899 aabb ccdd eeff 0123456789ABCDEF
00000000: 0000 0000 0000 0000 0000 0000 ............ three
```

Note that these indexes get reset every time `dump :val` gets executed.

A function `dumpval` is also provided in order to ease accessing the values whose bytes we dump. It has prototype:

```
dumpval (int<32> val = -1) any
```

Where `val` is the index of a value whose bytes have been printed by the last `dump :val` command. The function returns that value. If no index is specified, then `dumpval` returns the value passed as `:val` instead of some of its constituents.

### 24.1.2 Presentation options for `dump`

By default, the hexadecimal display shows two bytes grouped together, and then a space. You can alter this behaviour using the `group_by` parameter.

```
(poke) dump :ascii 0 :size 0x40#B :group_by 4#B
```

```
00000000: 68f19a63 dfb28886 c466631c a7fdd5c7 h...c.*..fc......
00000010: 0c7b746a 0adb03ca f5b1ff14 6166fa07 0utj........af...
00000020: 0dd3cfbd 8eff46a2 4152a81d 471beddf ......F.AR...G...
00000030: a0501cae 8bfec6f 7a4f5701 45ba9fc3 .P......ozOW.E...
```
Another parameter is the `cluster_by` argument. By setting `cluster_by` to $n$, this causes `dump` to display an additional space after the $n$th group has been displayed, and also in the corresponding position in the ASCII display:

```
(poke) dump :size 0x40#B :group_by 2#B :cluster_by 4
76543210 0011 2233 4455 6677 8899 aabb cccd eeff 01234567 89ABCDEF
00000000: 91b8 540d d4dc 49ae 3320 ba7d efd1 16ab ..T...I. 3 .}....
00000010: b1a8 5ea0 5846 8bea f741 3f80 42bc 201f ..^.XF.. .A?.B. .
00000020: 6e5e fa50 23fb f16a d380 be8c fc98 d195 n^.P#..j ..........
00000030: 7bbf fa3e 3fc2 43a4 2a1e 9763 2bd6 5d24 {..>?.C. *..c+.
```

Another variable that the user can customize is `pk_dump_nonprintable_char`. It defaults to `'.'`, and contains the character to use in the ASCII dump to represent a non-printable character.

Not all bytes from an IO space can be read, depending on the kind of IO device. When `dump` cannot read a byte it will print `pk_dump_unknown_byte` instead, which is a string.

If the variable `pk_dump_addr_hyperlinks` is 1 then the `dump` command will emit hyperlinks in the printed bytes. Clicking on a byte value will result in the address of that byte to be inserted at the prompt.

If you have a personal preference on how memory dumps should appear, you can set the relevant `pk_dump_*` variables. These global variables serve as the defaults for `dump`, so this way, you will not need to explicitly pass them when you call the function.

### 24.2 copy

The command `copy` allows to copy regions of data inside an IO space, or between different IO spaces.

This command has the following synopsis:

```
copy [:from offset] [:to offset] [:size offset]
 [:from_ios ios] [:to_ios ios]
```

All arguments are optional. When invoked with no arguments, `copy` does nothing.

The arguments `from` and `size` determine the region to copy. By default, this region is taken from the current IO space, but this can be overwritten using the optional `from_ios` argument.

The argument `to` tells `copy` where to copy the stuff. It defaults to `from`. Again, this offset is applied to the current IO space by default, but this can be overwritten using the `to_ios` argument.

Note that it is allowed for the source and destination ranges to overlap.

### 24.3 save

Use the `save` command in order to write a region from an IO space into a file in your file system.

This command has the following synopsis:

```
save [:ios ios] [:from offset] [:size offset] [:file string]
 [:append bool] [:verbose bool]
```

All arguments are optional. When invoked with no arguments, `save` does nothing.

The arguments `from` and `size` are used to determine the region of the IO space to save. This is how you would extract and save the contents of an ELF section to a file `out.text`:

```
(poke) var s = elf_section_by_name (Elf64_Ehdr @ 0#B, ".text")
(poke) save :file "out.text" :from s.sh_offset :size s.sh_size
```

Both `from` and `size` are arbitrary offsets. You should keep in mind however that files are byte oriented. Therefore saving, say, nine bits to a file will actually write two bytes.
By default `save` will extract the data from the current IO space. However, it is possible to specify an alternative IOS by using the `ios` argument.

By default `save` will truncate the output file, if it exists, before starting writing. If the argument `append` is set as true, however, it will append to the existing contents of the file. In this case, the file should exist.

### 24.4 sdiff

The `sdiff` command provides structured byte differences between two mapped values.

This command has the following synopsis:

```
    sdiff :a any :b any [:group_by offset] \\
             [:values bool]
```

Where `:a` and `:b` are two mapped values of the same type.

By default, the bytes are shown in the diff separated by white characters. You can alter this behaviour using the `group_by` parameter.

If `values` is true, then include field interpreted values in the diff output.

If the two values are not mapped, this command raises `E_no_map`. If the two values are not of the same type, the output will probably not be meaningful.

### 24.5 extract

Use the `extract` command in order to create a temporary memory IO space with the contents of a mapped value.

This command has the following synopsis.

```
    extract :val val [:to ios_name]
```

Where `:val` is a mapped value, and `:to` is the name of the memory IOS to create (or use). The contents of `value` are copied to the beginning of the memory IOS `ios_name`.

If no `:to` argument is specified, or if it is the empty string, then the `extract` command will generate a suitable unique name and use it.

### 24.6 scrabble

The `scrabble` command rearranges portions of an IO space based on a transformation defined by a pair of patterns.

This command has the following synopsis:

```
    scrabble [:from offset] [:size offset] \\
              [:from_pattern string] [:to_pattern string] \\
              [:ent_size offset] \\
              [:from_ios ios] [:to_ios ios]
```

The optional arguments are documented below.

`:from offset`

Beginning of the range in the origin IO space from where to start rearranging units. Defaults to `0#B`.

`:size offset`

Size of the range to scrabble in the origin IO space. Defaults to `0#B`.

`:from_pattern string`

String specifying a sequence of units. Each character is an unit. Defaults to `""`. 

:to_pattern string
   String specifying the scrabbled units. Each character is an unit. If a character that
doesn’t appear in the from_pattern is found in this string, it is ignored. Defaults
to from_pattern.

:ent_size offset
   Size of the entities to scrabble around. Defaults to 1#B.

:from_ios ios
   IO space from where to obtain the data to scrabble. Defaults to the current IO
   space.

:to_ios ios
   The IO space to where write the scrabbled data. Defaults to from_ios.
25 The Poke Language

25.1 Source Code Encoding

poke reads program source as UTF-8 encoded text. Program sources can span over multiple lines. A line is a sequence of characters terminated by an end-of-line. End-of-line can be a single new-line character (ASCII LF or \n), the UNIX form, or pair of ASCII CR and ASCII LF (\r\n) characters, the Windows form.

25.2 Integers

Most of the values manipulated in Poke programs are whole numbers, also typically known as integers in computing parlance. This is because integers are pervasive in binary formats, often featuring unusual characteristics in terms of size and/or alignment. Single bits denoting flags or packed small integers are good examples of this. In order to ease the manipulation of such entities, and unlike most programming languages, Poke provides integer types of any number of bits and a rich set of accompanying operators.

25.2.1 Integer Literals

Integers literals can be expressed in several numeration bases.

Decimal numbers use the usual syntax [1-9] [0-9]*. For example, 2345.

Octal numbers are expressed using a prefix 0o (or 0O) followed by one or more digits in the range [0-7]. Examples are 0o0, 0o100 and 0o777.

Hexadecimal numbers are expressed using a prefix 0x (or 0X) followed by one or more hexadecimal digits in the range [0-f]. Examples are 0x0 and 0xfe00ffff. Note that both the x in the prefix and the letters in the hexadecimal number are case insensitive. Thus, 0XdeadBEEF is a valid (but ugly as hell) literal.

Binary numbers are expressed using a prefix 0b (or 0B) followed by one or more binary digits in the range [0-1]. Examples of binary literals are 0b0 and 0B010.

Negative numbers, of any numeration base, are constructed using the minus operator as explained below. Therefore the minus symbol - in negative numbers is not part of the literal themselves.

25.2.1.1 The digits separator _

The character _ can appear anywhere in a numeric literal except as the first character. It is ignored, and its purpose is to make it easier for programmers to read them:

0xf000_0000_0000_0000
0b0000_0001_0000_0001

25.2.1.2 Types of integer literals

The type of a numeric literal is the smallest signed integer capable of holding it, starting with 32 bits, in steps of powers of two and up to 64 bits.¹

So, for example, the value 2 has type int<32>, but the value 0xffff_ffff has type int<64>, because it is out of the range of signed 32-bit numbers.

A set of suffixes can be used to construct integer literals of certain types explicitly. L or l is for 64-bit integers. H or h is for 16-bit integers (also known as halves). B or b is for 8-bit integers

¹ Rationale: the width of a C “int” is 32 bits in most currently used architectures, and binary data formats are usually modelled after C.
(also known as bytes) n or N is for 4-bit integers (also known as nibbles) and t or T is for 1-bit integers (also known as bits).

Thus, 10L is a 64-bit integer with value 0x0000_0000_0000_000A, 10H is a 16-bit integer with value 0x000A and 10b is a 8-bit integer with value 0x0A.

Similarly, the signed or unsigned attribute of an integer can be explicitly specified using the suffix u or U (the default are signed types). For example 0xffff_ffffU has type uint<32> and 0ub has type uint<8>. It is possible to combine width-indicating suffixes with signedness suffixes: 10UL denotes the same literal as 10LU. Note that bit constants (suffix t or T) are always unsigned and do not require U.

The above rules guarantee that it is always possible to determine the width and signedness of an integer constant just by looking at it, with no ambiguity.

25.2.2 Characters

8-bit unsigned integers can use an alternative literal notation that is useful when working with ASCII character codes. Printable character codes can be denoted with ‘c’.

Non-printable characters can be expressed using escape-sequences. The allowed sequences are:

\n New-line character (ASCII 012).
\t Tab character (ASCII 011).
\\ The backslash character.
\[0-9] [0-9]? [0-9]?
Character whose ASCII code is the specified number, in octal.

Examples:

'\n'
'\t'
'\\'
'\0'

The type of a character literal is always char, aka uint<8>.

25.2.3 Booleans

Like in C, truth values in Poke are encoded using integers. Zero (0) denotes the logical value “false”, and any integer other than zero denotes the logical value “true”.

25.2.4 Integer Types

Most general-purpose programming languages provide a small set of integer types, each featuring a range corresponding to strategic storage sizes: basically, signed and unsigned variants of 8, 16, 32, 64 bits. As we have seen in the previous sections, suffixes like H or L are used in Poke for that purpose.

However, in conventional programming languages when integers having an “odd” width (like 13 bits, for example) get into play for whatever reason, the programmer is required to use the integer arithmetic operators (and sometimes bit-wise operators) herself, in a clever way, in order to achieve the desired results.

Poke, on the contrary, provides a rich set of integer types featuring different widths, in both signed and unsigned variants. The language operators are aware of these types, and will do the right thing when operating on integer values having different widths.
Unsigned integer types are specified using the type constructor `uint<n>`, where `n` is the number of bits. `n` should be an integer literal in the range \([1,64]\). Examples:

```pokena
uint<1>
uint<7>
uint<64>
```

Similarly, signed integer types are created using the type constructor `int<n>`, where `n` is the number of bits. `n` should be an integer literal in the range \([1,64]\). Examples:

```pokena
int<1>
int<8>
int<64>
```

Note that expressions are not allowed in the type integral constructor parameters. Not even constant expressions. Thus, things like `int<foo>` and `uint<2+3>` are not allowed.

### 25.2.5 Casting Integers

The right-associative unary operator cast `as` can be used to derive a new integer value having a different type from an existing value.

For example, this is how we would create a signed 12-bit integer value holding the value 666:

```pokena
(poke) 666 as int<12>
(int<12>) 666
```

Note that the 666 literal is originally a 32-bit signed integer. The cast performs the conversion.

Casts between integer types are always allowed, and never fail. If the new type is narrower than the existing type, truncation may be performed to accommodate the value in its new type. For example, the expression `0x8765_4321 as uint<16>` evaluates to `0x4321`. If the new type is wider than the existing type, either zero-extension or sign-extension is performed depending on the signedness of the operand.

The semantics of the sign-extension operation depends on the signedness of the value being converted, and on the currently selected encoding for negative numbers.

When using two’s complement encoding, converting a signed value will always sign-extend regardless of the signedness of the target type. Thus:

```pokena
(poke) -2H as uint<32>
0xffffffffeU
(poke) -2H as int<32>
0xffffffff
```

Likewise, converting an unsigned value will always zero-extend regardless of the signedness of the target type. Thus:

```pokena
(poke) 0xffffUH as uint<32>
0xfffffU
(poke) 0xffffUH as int<32>
0xffff
```

### 25.2.6 Relational Operators

The following binary relational operators are supported on integer values, in descending precedence order:

- Equality `==` and inequality `!=`.
- Less than `<` and less or equal than `<=`.
- Greater than `>` and greater or equal than `>=`.
When applied to integer and character values, these operators implement an arithmetic ordering.

These operators resolve in boolean values encoded as 32-bit integers: 0 meaning false and 1 meaning true.

### 25.2.7 Arithmetic Operators

The following left-associative binary arithmetic operators are supported, in descending precedence order:

- Exponentiation **, multiplication *, integer division /, integer ceil-division /\(^\) and modulus %.
- Addition + and subtraction −.

In all the binary arithmetic operations automatic promotions (coercions) are performed in the operands as needed. The rules are:

- If one of the operands is unsigned and the other operand is signed, the second is converted to an unsigned value.
- If the size in bits of one of the operands is bigger than the size of the other operand, the second is converted to the same number of bits.

The following right-associative unary arithmetic operators are supported:

- Unary minus − and unary plus +.

Finally, pre-increment, pre-decrement, post-increment and post-decrement operators ++ and −− are supported.

### 25.2.8 Bitwise Operators

The following left-associative bitwise binary operators are supported, in descending precedence order:

- Bitwise shift left <<, and bitwise shift right .>>.
- Bitwise AND &.
- Bitwise exclusive OR ^.
- Bitwise inclusive OR |.
- Bitwise concatenation :::

Both << and .>> operators perform logical shifting. Unlike in many other programming languages, arithmetic right-shifting operators are not provided. This means that right shifting always inserts zeroes at the most-significant side of the value operand, whereas left shifting always inserts zeroes at the least-significant side of the value operand.

Left shifting by a number of bits equal or bigger than the size of the value operand is an error, and will trigger either a compile-time error or a run-time E_out_of_bounds exception. This does not apply to right shifting.

Bitwise concatenation works with any integral type, of any bit length.

The following right-associative unary bitwise operators are supported:

- Bitwise complement ~.

### 25.2.9 Boolean Operators

The following left-associative, short-circuited binary logical operators are supported, in descending precedence order:

- Logical implication: =>.
- Logical AND: &\&.
• Inclusive OR: ||.

The following right-associative unary logical operators are supported:
• Logical negation !.

### 25.2.10 Integer Attributes

The following attributes are defined for integer values.

- **size**
  Gives an offset with the storage occupied by the string. This includes the terminating null. Examples:
  ```
  (poke) 10'size
  0x20UL#b
  (poke) 10N'size
  0x4UL#b
  (poke) (10 as int<1>)'size
  0x1UL#b
  ```

- **signed**
  Gives 1 if the value is a signed integer, 0 otherwise. Examples:
  ```
  (poke) 10'signed
  1
  (poke) 10UL'signed
  0
  ```

- **mapped**
  Always 0 for integers. (see Section 25.16 [Mapping], page 179).

- **length**
  Always 1UL for integers.

### 25.3 Offsets

Poke uses united values to handle offsets and data sizes. This is a very central concept in poke.

#### 25.3.1 Offset Literals

Poke provides a convenient syntax to provide united values, which are called offsets (because in a binary editor you mostly use them to denote offsets in the file you are editing):

- `12#B`
- `7#b`
- `1024#KB`

The offsets above denote twelve bytes, seven bits and one thousand twenty four kilobytes, respectively. The unit can be separated from the magnitude by blank characters, so you can write the following instead if you are so inclined:

- `12  #B`
- `7  #b`
- `(1024 * 1024)  #Kb`

Note how the magnitude part of an offset doesn’t need to be constant. If the variable `a` contains an integer, this is how you would denote “a bytes”:

- `a#B`

In the offset syntax units are specified as `#unit`, where `unit` is the specification of an unit. See the next section for details.

#### 25.3.2 Offset Units

There are several ways to express the unit of an offset, which is always interpreted as a multiple of the basic unit, which is the bit (one bit).
25.3.2.1 Named Units

The first way is to refer to an unit by name. For example, \(2\text{#B}\) for two bytes. Units are defined using the unit construction:

\[
\text{unit } \text{name} = \text{constant_expression} [, \text{name} = \text{constant_expression}]...;
\]

where \text{name} is the name of the unit, and \text{constant_expression} is a constant expression that should evaluate to an integral value. The resulting value is always coerced into an unsigned 64-bit integer.

Note that unit names live in a different namespace than variables and types. However, when a given name is both a type name and an unit name in an unit context, the named unit takes precedence:

\[
\text{(poke)} \text{type } \text{xx} = \text{int} \\
\text{(poke)} \text{unit } \text{xx} = 2 \\
\text{(poke)} 1\#\text{xx} \\
1\#2
\]

Many useful units are defined in the standard library. See Section 26.3 [Standard Units], page 199.

25.3.2.2 Arbitrary Units

It is also possible to express units in multiples of the base unit, which is the bit. Using this syntax, it becomes possible to express offsets in any arbitrary unit, as disparate as it may seem:

\[
17\#3 \\
0\#12 \\
8\#1
\]

That’s it: 17 units of 3 bits each, zero units of 12 bits each, and eight units of 1 bit each. Note that the unit should be greater than 0.

25.3.2.3 Types as Units

But then, why stop there? Poking is all about defining data structures and operating on them... so why not use these structures as units as well? Consider the following struct:

\[
\text{type Packet} = \text{struct} \{ \text{int i}; \text{long j}; \};
\]

The size of a \text{Packet} is known at compile time (which is not generally true for Poke structs). Wouldn’t it be nice to use it as a unit in offsets? Sure it is:

\[
23\#\text{Packet}
\]

The above is the size occupied by 23 packets. Any type whose size is known at compile time can be specified as an offset unit.

Expressing offsets as united values also relieves the programmer from doing many explicit unit conversions: poke can do them for you. Consider for example an ELF section header. One of its fields is the size of the described section, in bytes:

\[
\text{type Elf64_Shdr} = \\
\text{struct} \\
\{ \\
\ldots \\
\text{offset<Elf64_Xword,B> sh_size;} \\
\ldots \\
\};
\]

If a given section is to contain, say, relocations with addends, we can set its size doing something like this:

\[
\text{shdr.sh_size} = 10\#\text{Elf64_Rela};
\]
Instead of doing the conversion to bytes explicitly.

If the magnitude of an offset is 1 then it is allowed to omit it entirely. To denote one kilobyte, for example, we can write \#KB.

### 25.3.3 Offset Types

Offset types are denoted as `offset<base_type, unit[, ref_type]`, where `base_type` is an integer type, `unit` the specification of an unit, and `ref_type` is an optional type of a referred value.

The offset base type is the type of the magnitude part of the united value. It can be any integer type, signed or unsigned, of any size.

The unit specification should be one of the unit identifiers that are allowed in offset literals (see above), a constant positive integer or the name of a Poke type whose size is known at compile time.

If a referred type is specified, this tells poke that the offset may be used in order to refer to a value stored on some IO space. This is similar to the notion of a pointer in other programming languages.

Let’s see some examples. A signed 32-bit offset expressed in bytes has type `offset<int<32>,B>`. An unsigned 12-bit offset expressed in kilobits has type `offset<uint<12>,Kb>`. The latter type can also be written using an explicit integer unit like in `offset<uint<12>,1024>`. Finally, a signed 64-bit offset in units of “packets”, where a packet is denoted with a Poke type `Packet` has type `offset<uint<64>,Packet>`.

An offset whose purpose is to refer to some data structure of type `Packet` stored in some IO space could have type `offset<uint<64>,B,Packet>`.

### 25.3.4 Casting Offsets

The right-associative unary operator cast as can be used to derive a new offset value having a different type from an existing value.

For example, this is how we would create a signed 12-bit offset in units bytes:

```pokelang
(poke) 1024#b as offset<int<12>,B>
(int<12>) 128#B
```

The same rules governing conversion of integers apply for the magnitude part. Depending on the unit, there can be truncation, like in:

```pokelang
(poke) 9#b as offset<int,B>
1#B
```

### 25.3.5 Offset Operations

Poke supports a little algebra for offsets.

#### 25.3.5.1 Addition and subtraction

The addition or subtraction of two offsets results in another offset. Examples:

```pokelang
(poke) 1#B + 1#b
9#b
```

```pokelang
(poke) 2#KB - 1024#B
1024#B
```

The unit of the result is the greatest common divisor of the units of the operands. The result offset is not a referring offset.

The operators ++ and --, in their prefix and suffix versions, can be applied to offsets as well. The step used in the increment/decrement is one unit.
25.3.5.2 Multiplication by a scalar

Multiplying an offset by a magnitude gives you another offset. Examples:

\[
\begin{align*}
\text{(poke) } & 8\text{#b} * 2 \\
& 16\text{#b} \\
\text{(poke) } & 16\text{#MB} * 0 \\
& 0\text{#MB}
\end{align*}
\]

The unit of the result is the same as the unit of the offset operand. The result offset is not a referring offset.

Note that multiplying two offsets is not supported. This makes sense, since computer memory is linear, and therefore it wouldn’t make any sense to have units like #B^2.

25.3.5.3 Division

Dividing two offsets gives you a magnitude. Examples:

\[
\begin{align*}
\text{(poke) } & 16\text{#b} / 1\text{#B} \\
& 2 \\
\text{(poke) } & 1024\text{#MB} / 512\text{#Mb} \\
& 16
\end{align*}
\]

Dividing offsets is the Pokish way of converting memory magnitudes between different units: just use units like you do when doing physics or working with units in other contexts.

For example, using the syntactic trick of omitting the magnitude (in which case it is assumed to be 1) it is very natural to write something like the following to convert from kilobits to bytes:

\[
\begin{align*}
\text{(poke) } & 24 \text{#Kb/#B} \\
& 3072
\end{align*}
\]

There is also a ceil-division operator for offsets, with the same semantics as the ceil-division for integers:

\[
\begin{align*}
\text{(poke) } & 10\text{#B} /\text{^} 3\text{#B} \\
& 4
\end{align*}
\]

25.3.5.4 Division by an integer

Dividing an offset by an integer gives you an offset. Example:

\[
\begin{align*}
\text{(poke) } & 8\text{#B} / 2 \\
& 4\text{#B}
\end{align*}
\]

The unit of the result is the unit of the offset operand. The result offset is not a referring offset.

25.3.5.5 Modulus

The modulus of two offsets gives you another offset with the expected semantics. Examples:

\[
\begin{align*}
\text{(poke) } & 9\text{#b} \% 1\text{#B} \\
& 1\text{#b} \\
\text{(poke) } & 1\text{#B} \% 9\text{#b} \\
& 8\text{#b}
\end{align*}
\]

The unit of the result is the greatest common divisor of the units of the operands. The result offset is not a referring offset.

25.3.6 Offset Attributes

The following attributes are defined for offset values.

size  

Gives an offset with the storage occupied by the offset. Examples:

\[
\begin{align*}
\text{(poke) } & 10\text{#B}'\text{size}
\end{align*}
\]
0x20UL#b
(poke) 10#B'magnitude
10
(poke) 2H#b'magnitude
2H

magnitude
Gives the magnitude part of the offset. Examples:
(poke) 10#B'magnitude
10
(poke) 2H#b'magnitude
2H

unit
Gives a number with the unit of the offset, expressed in bits. Examples:
(poke) 10#B'unit
8UL
(poke) 2H#b'unit
1UL

mapped
Always 0 for offsets. (see Section 25.16 [Mapping], page 179).

length
Always 1UL for offsets.

ref ([IOS])
If the value is a referring offset, then the application of the 'ref attribute implies the mapping of the referred value.
The attribute gets an optional argument which is the IO space to use when mapping the referred value. If this argument is not provided then the current IO space is assumed. The application of this attribute may result in a E_no_ios exception.

25.4 Strings
Poke supports a notion of strings which is very similar to the C programming language: a string value is a sequence of characters that is terminated by the so-called null character.

The standard library provides functions which process strings. See Section 26.6 [String Functions], page 202.

25.4.1 String Literals
NULL-terminated sequences of ASCII codes can be denoted using the following syntax:
"foo"

Poke string values are very similar to C strings. They comprise a sequence of 8-bit character codes, terminated by the value 0UB.

The following escape sequences are supported inside string literals:
\n Denotes a new line character.
\t Denotes an horizontal tab.
\\ Denotes a backlash \ character.
\" Denotes a double-quote " character.
\num num is a number in the range 1 to 255 (inclusive) in base 8.
\xnum num is a number in the range 1 to 255 (inclusive) in base 16.

Strings cannot contain 0UB character, and inserting one using escape sequences (\0 or \x0) leads to compilation error.
25.4.2 String Types

Every string value in Poke is of type `string`.

25.4.3 String Indexing

Poke supports accessing the characters in a string using the array indexing notation. The indexes are in the \([0, n]\) range, where \(n\) is the length of the string minus one. Note the length doesn’t include the null character, *i.e.* it is not possible to access the terminating null. Examples:

\[
\begin{align*}
(\text{poke}) & \ "\text{foo}\"[0] \\
& 0x66\text{UB} \\
(\text{poke}) & \ "\text{foo}\"[1] \\
& 0x6f\text{UB}
\end{align*}
\]

If the passed index is less than zero or it is too big, an `E_out_of_bounds` exception is raised:

\[
\begin{align*}
(\text{poke}) & \ "\text{foo}\"[-1] \\
& \text{unhandled out of bounds exception} \\
(\text{poke}) & \ "\text{foo}\"[3] \\
& \text{unhandled out of bounds exception}
\end{align*}
\]

Poke also provides a way to refer to a character in a string by the offset the character occupies in the string. This is done by using as index an expression that evaluates to an offset value. This value is then implicitly promoted to have an unsigned 64-bit magnitude and unit bits whenever needed. If no character starts *exactly* at the provided offset then an `E_out_of_bounds` exception is raised.

25.4.4 String Concatenation

Strings can be concatenated using the `+` operator. This works like this:

\[
\begin{align*}
(\text{poke}) & \ "\text{foo}\" + \ "\text{bar}\"
\end{align*}
\]

"foobar"

Note how the null character terminating the first string is removed. Therefore, the length of the concatenation of two given strings of lengths \(N\) and \(M\) is always \(N+M-1\).

Concatenation and indexing are useful together for building strings. A string can be created empty, and additional characters added to it by means of concatenation:

\[
\begin{align*}
(\text{poke}) & \ \text{var} \ \text{bytes} = \ "\"; \\
(\text{poke}) & \ \text{bytes} = \ \text{bytes} + \ 'x' \ as \ \text{string};
\end{align*}
\]

Then, we can retrieve characters from the string we built using indexing:

\[
\begin{align*}
(\text{poke}) & \ \text{bytes}[0] \\
& 0x78\text{UB}
\end{align*}
\]

Additionally, the `*` operator allows to “multiply” a string by concatenating it with itself a given number of times. This works like this:

\[
\begin{align*}
(\text{poke}) & \ "\text{foo}\" \ * \ 3
\end{align*}
\]

"foofoofoo"

\[
\begin{align*}
(\text{poke}) & \ "\text{foo}\" \ * \ 0
\end{align*}
\]

""

This is useful for building strings whose length is not known at compile time. For example:

\[
\begin{align*}
\text{fun} & + make_empty_string = (\text{int} \ \text{length}) \ \text{string}:
\{ \\
& \ \text{return} \ " \ " \ * \ \text{length}; \\
\}
\end{align*}
\]
25.4.5 String Attributes

The following attributes are defined for string values.

**length**
Gives the number of characters composing the string, not counting the terminating null. Examples:

```poke
(poke) "foo"'length
3UL
(poke) ""'length
0UL
```

**size**
Gives an offset with the storage occupied by the string. This includes the terminating null. Examples:

```poke
(poke) "foo"'size
32UL\#b
(poke) ""'size
8UL\#b
```

**mapped**
Always 0 for strings. (see Section 25.16 [Mapping], page 179).

25.4.6 String Formatting

Poke provides a built-in function `format` that can be used in order to format, or build, a string value that is derived from a set of zero or more Poke values:

```
format (fmt[, value...])
```

Where `fmt` is a format string that interpreted verbatim but for predefined format tags which start with `%`. These format tags are interpreted especially. See Section 25.19.2 [printf], page 192.

Example:

```
var s = format ("Age is %i32d.", 66);
```

The value of the variable `s` is "Age is 66."

25.5 Arrays

Arrays are homogeneous collections of values.

25.5.1 Array Literals

Array literals are constructed using the following syntax:

```
[exp, exp...]
```

where `exp` is an arbitrary expression.

For example, `[1,2,3]` constructs an array of three signed 32-bit integers. Likewise, `['a','b','c']` constructs an array of three unsigned 8-bit integers (characters). For convenience, a trailing comma is accepted but not required.

The type of the array literal is inferred from the type of its elements. Accordingly, all the elements in an array literal must be of the same type. Examples of invalid array literals, that will raise a compilation-time error if evaluated, are:

```
[1,2u,3]
[1,0xffff_ffff,3]
['a','b','c']
```

Array literals must contain at least one element. Accordingly, `[]` is not a valid array literal.

This is how a 3x3 matrix could be constructed using an array of arrays:

```
[[1,2,3],[4,5,6],[7,8,9],]
```
It is possible to refer to specific elements when constructing array literals. For example, 
\[1,2,3,.[3] = 4\] denotes the same array as \[1,2,3,4\].

This allows creating arrays without having to specify all its elements; every unspecified element takes the value of the first specified element to its right. For example, \[.\[2\] = 2\] denotes the same array as \[2,2,2\].

Note that an array element can be referenced more than once. When that happens, the final value of the element is the last specified. For example, \[1,2,3,.[1]=10\] denotes the array \[1,10,3\].

25.5.2 Array Types

There are three different kinds of array types in Poke.

Unbounded arrays have no explicit boundaries. Examples are int[] or Elf64_Shdr[]. Arrays can be bounded by number of elements specifying a Poke expression that evaluates to an integer value. For example, int[2]. Finally, arrays can be bounded by size specifying a Poke expression that evaluates to an offset value. For example, int[8#B].

25.5.2.1 Writing unbounded array literals

The type of an array literal is always bounded by number of elements. For example, the type of \[1,2,3\] is int[3]. If what we want is an unbounded array literal we can obtain it with a case like \[1,2,3\] as int[].

25.5.2.2 Array boundaries and closures

Poke arrays are rather peculiar. One of their seemingly bizarre characteristics is the fact that the expressions calculating their boundaries (when they are bounded) evaluate in their own lexical environment, which is captured. In other words: the expressions denoting the boundaries of Poke arrays conform closures. Also, the way they evaluate may be surprising. This is no capricious.

When an array type is bounded, be it by number of elements or by size, the expression indicating the boundary doesn’t need to be constant and it can involve variables. For example, consider the following type definition:

\[
\text{var } N = 2; \\
\text{type List = int[N*2];}
\]

Let’s map a List at some offset:

(poke) List @ 0#B
[0x746f6f72,0x303a783a,0x723a303a,0x3a746f6f]

As expected, we get an array of four integers. Very good, obviously the boundary expression \(N*2\) got evaluated when defining the type List, and the result of the evaluation was 4, right?. Typical semantics like in my garden variety programming language...? Right??

Well, not really. Let’s modify the value of \(N\) and map a List again... .

(poke) N = 1
(poke) List @ 0#B
[0x746f6f72,0x303a783a]

Yes, The boundary of the array type changed... on, this is Poke, was you really expecting something typical? ;)

What happens is that at type definition time the lexical environment is captured and a closure is created. The body of the closure is the expression. Every time the type is referred, the closure is re-evaluated and a new value is computed.

Consequently, if the value of a variable referred in the expression changes, like in our example, the type itself gets updated auto-magically. Very nice but, why is Poke designed like this? Just to impress the cat? No.
In binary formats, and also in protocols, the size of some given data is often defined in terms of some other data that should be decoded first. Consider for example the following definition of a `Packet`:

```go
type Packet =
struct {
  byte size;
  byte[size] payload;
};
```

Each packet contains a 8-bit integer specifying the size of the payload transported in the packet. The payload, a sequence of `size` bytes, follows.

In struct types like the above, the boundaries of arrays depend on fields that have been decoded before and that exist, like variables, in the lexical scope captured by the struct type definition (yes, these are also closures, but that’s for another article.) This absolutely depends on having the array types evaluate their bounding expressions when the type is used, and not at type definition time.

To show this property in action, let’s play a bit:

```go
(poke) var data = byte[4] @ 0#B
(poke) data[0] = 2
(poke) data[1] = 3
(poke) data[2] = 4
(poke) data[3] = 5
(poke) dump
76543210 0011 2233 4455 6677 8899 aabb ccdd eeff
00000000: 0203 0405 0000 0000 0000 0000 0000 0000
00000010: 0000 0000 0000 0000 0000 0000 0000 0000
(poke) var p1 = Packet @ 0#B
(poke) var p2 = Packet @ 1#B
(poke) p1
Packet {size=0x2UB,payload=[0x3UB,0x4UB]}
(poke) p2
Packet {size=0x3UB,payload=[0x4UB,0x5UB,0x0UB]}
```

Now, let’s change the data and see how the sizes of the payloads are adjusted accordingly:

```go
(poke) data[0] = 1
(poke) data[1] = 0
(poke) p1
Packet {size=0x1UB,payload=[0x0UB]}
(poke) p2
Packet {size=0x0UB,payload=[]}
```

So, as we have seen, Poke’s way of handling boundaries in array types allows data structures to adjust to the particular data they contain, so usual in binary formats. This is an important feature, that gives Poke part of its feel and magic.

### 25.5.3 Casting Arrays

There are two kinds of casts for array values:

- Cast to array types that may have a different bounding.
- Cast of array of integers or integral structs to an integral type.

For example, we have seen that the type of an array literal is always bounded by a constant number of elements. Thus the type of `[1,2,3]` is `int[3]`. 
We could cast the value above to an unbounded array type by doing:

```plaintext
[1,2,3] as int[]
```

Or to an array bounded by size:

```plaintext
[1,2,3] as int[12#B]
```

Of course trying to cast an array value to a type for which the bounding restrictions will fail. This will give you a compile-time error:

```plaintext
[1,2,3] as int[4]
```

And this will result in a run-time error:

```plaintext
(poke) [1,2,3] as int[13#B]
unhandled conversion error exception
```

Now let’s see how Poke reinterprets integral arrays as integers:

```plaintext
(poke) [0xdeUB,0xadUB] as uint16
0xdeadUH
(poke) [0xdeUB,0xadUB,0UB] as int
0xdead00
```

Trying to cast an array with a size larger than 64-bit will result in an error:

```plaintext
(poke) [1,2,3] as int
unhandled conversion error exception
arrays bigger than 64-bit cannot be casted to integral types
```

It also works for nested arrays and arrays of integral structs (See Section 25.6.11 [Integral Structs], page 155):

```plaintext
(poke) type Foo = struct uint { int16 hi; int16 lo; };
(poke) [[Foo{ hi=0xdeadH, lo=0xbeefH}], [Foo{}]] as ulong
0xdeadbeef00000000UL
```

The way it works is like putting all array elements in an `uint<64>` number and then casting that number to the destination integral type.

### 25.5.4 Array Constructors

Array literals can only specify arrays which a constant number of elements. They also require initial values for their elements, and it is also not possible to construct an array literal denoting an empty array of some given type.

Array constructors provide a suitable way to build such array values. The syntax is:

```plaintext
array_type ([value])
```

Where `array_type` is an array type, or the name of an array type, and `value` is an optional argument that specify the value to which the elements of the new array are initialized. If no value is provided in the constructor then default values are calculated.

If the boundaries of the array can’t be satisfied while constructing, `E_constraint` is raised.

Examples:

```plaintext
(poke) int[] ()
[]
(poke) int[2] ()
[0,0]
(poke) int[2](10)
[10,10]
(poke) offset<int,B>[2](16#b)
[2#B,2#B]
(poke) string[3] ()
```

...
Note that array constructors are implicitly involved when you construct a struct or union value that contains a field whose type is an array. For example, consider the following type:

```pascal
type Packet =
  struct
    byte sz;
    byte[sz] data;
  end;
```

When a packet is constructed using `Packet {}` the `data` field of the struct is also constructed, implicitly using a constructor for the array type `byte[sz]`.

### 25.5.5 Array Comparison

The equality operator (==) and the inequality operator (!=) can be applied to arrays. Examples:

- `(poke) [1,2,3] == [1,2,3]` 1
- `(poke) [[1,2],[3,4]] != [[5,6],[7,8]]` 1

Note that the array elements are compared recursively.

### 25.5.6 Array Indexing

Arrays are indexed using the usual notation, providing an index enclosed between square brackets with [ and ]:

- `(poke) [1,2,3][0]` 1
- `(poke) [1,2,3][8#B]` 2

#### 25.5.6.1 Indexing an array by number of element

Indexing by number of element is performed by providing as index an expression that evaluates to an integral value. This value is then implicitly promoted to an unsigned 64-bit integer when needed.

The valid range for the index is `[0,n]` where `n` is the number of elements stored in the array minus one. If the passed integer is out of that range, an `E_out_of_bounds` exception is raised:

- `(poke) [1,2,3][-1]` unhandled out of bounds exception
- `(poke) [1,2,3][3]` unhandled out of bounds exception

#### 25.5.6.2 Indexing an array by offset of element

Poke also provides a way to refer to the element of an array by the offset where the element appears inside the array. This is done by providing as index an expression that evaluates to an offset value. This value is then implicitly promoted to an offset with magnitude unsigned 64-bit integer and bit unit when needed.

If there is not element in the indexed array that starts `exactly` at the given offset then an `E_out_of_bounds` exception is raised.
25.5.7 Array Trimming

Indexing is used to fetch elements from arrays. Another operation, called *trimming*, allows you to extract a subset of the array, as another array.

Trims use the following notation, where a range is specified between square brackets. The left sides of the range are closed, whereas the right sides of the range are open:

(poke) \[1,2,3\] [0:2]
  \[1,2\]
(poke) \[1,2,3\] [1:2]
  \[2\]
(poke) \[1,2,3\] [0:3]
  \[1,2,3\]

If the minimum side of the range is omitted, it is assumed to be zero. If the maximum side of the range is omitted, it is assumed to be the length of the trimmed array:

(poke) \[1,2,3\] [:2]
  \[1,2\]
(poke) \[1,2,3\] [1:]
  \[2,3\]
(poke) \[1,2,3\] [:]
  \[1,2,3\]

The elements of the base array and the trimmed sub-array are copied by shared value, exactly like when passing arguments to functions. This means that for simple types, copies of the elements are done:

(poke) var a = \[1,2,3\]
(poke) var s = a[1:2]
(poke) s[0] = 66
(poke) a
  \[1,2,3\]

However, for complex types like arrays and structs, the values are shared:

(poke) var a = Packet[] @ 0#B
(poke) var s = a[1:2]
(poke) s[0].field = 66
(poke) a[1].field
  66

There is an alternative syntax that can be used in order to denote trims, in which the length of the trim is specified instead of the index of the second element. It has this form:

(poke) \[1,2,3\] [0+:3]
  \[1,2,3\]
(poke) \[1,2,3\] [1+:2]
  \[2,3\]
(poke) \[1,2,3\] [1+:0]
  []

25.5.8 Array Elements

The `in` operator can be used to determine whether a given element is stored in an array. Examples:

(poke) 2 in \[1,2,3\]
  1
(poke) 2 in \[4,5,6\]
  0
(poke) 10#b in [1#B] #! Promotion doesn't happen. !#
<stdin>:1:1: error: invalid operand in expression
<stdin>:1:1: error: expected offset<int<32>,8>, got offset<int<32>,1>

### 25.5.9 Array Concatenation

The operator `+` can be used to build new arrays resulting from the concatenation of the elements of two arrays given as operands:

```
(poke) [1,2] + [3,4,5]
[1,2,3,4,5]
```

The two arrays given as operands shall have the same elements of the same type. The resulting array is always unbounded.

### 25.5.10 Array Attributes

The following attributes are defined for array values.

- **size**
  
  Gives an offset with the storage occupied by the complete array. Example:
  ```
  (poke) [1,2,3]'size
  96UL#b
  ```

- **length**
  
  Gives the number of elements stored in the array. Example:
  ```
  (poke) [1,2,3]'length
  3
  ```

- **mapped**
  
  Boolean indicating whether the array is mapped. Examples:
  ```
  (poke) var a = [1,2,3]
  (poke) var b = int[3] @ 0#B
  (poke) a'mapped
  0
  (poke) b'mapped
  1
  ```

- **strict**
  
  Boolean indicating whether the array is mapped in strict mode. Examples:
  ```
  (poke) var a = int[3] @ 0#B
  (poke) a'strict
  1
  (poke) var a = int[3] @! 0#B
  (poke) a'strict
  0
  ```

- **elem (idx)**
  
  Element occupying the position `idx` in the array. Note that this attribute evaluates to a value of type `any`.

- **eoffset (idx)**
  
  Offset of the element identified by the index `idx` in the array. Examples:
  ```
  (poke) [1,2,3]'eoffset (1)
  32#b
  ```
  
  If the provided index is out of bounds then `E_out_of_bounds` is raised.

- **esize (idx)**
  
  Size of the element identified by the index `idx` in the array. Examples:
  ```
  (poke) ["foo","x",""]'esize (1)
  16#b
  ```
  
  If the provided index is out of bounds then `E_out_of_bounds` is raised.
ename (idx)
The string "[idx]".
If the provided index is out of bounds then **E_out_of_bounds** is raised.

### 25.5.11 Arrays as Stacks

Array values can be manipulated as stacks using two operators: **apush** and **apop**.

The **apush** operator gets an array and a value and appends the value into the array. Note it has a destructive side-effect in the array value, and also it returns the modified value:

```poken
(poke) var a = [1,2,3]
(poke) apush (a, 4)
[1,2,3,4]
(poke) a
[1,2,3,4]
```

the **apop** operators gets an array and removes the last value of the array. If the given array is empty then **E_out_of_bounds** is raised. As with **apush**, the operation has the side effect of modifying the given array and also it returns the popped element:

```poken
(poke) var a = [1,2,3]
(poke) apop (a)
3
(poke) apop (a)
2
(poke) apop (a)
1
(poke) apop (a)
unhandled out of bounds exception
```

### 25.6 Structs

Structs are the main abstraction that Poke provides to structure data. They contain heterogeneous collections of values.

#### 25.6.1 Struct Types

A simple struct type definition in Poke looks like:

```poken
type Packet =
struct
{
    byte magic;
    uint<16> length;
    byte[length] data;
}
```

The above defines a “Packet”, which consists on a magic number encoded in a byte, a length encoded in an unsigned 16-bit integer, and an array of **length** bytes, which is the payload of the packet.

Each entry in the struct type above defines a **struct field**.

Each field has a type, which is mandatory, and a name, which is optional. Fields without names are not accessible (not even within the struct itself) but they are handy for expressing esoteric padding. See Section 4.11 [Padding and Alignment], page 64. Example:

```poken
type Imm64 =
struct
{
```
It is not allowed to have several fields with the same name in the same struct. The compiler will complain if it finds such an occurrence.

25.6.2 Struct Constructors

Once a struct type gets defined, there are two ways to build struct values from it. One is mapping. See Section 25.16.4 [Mapping Structs], page 184. The other is using a struct constructor, which is explained in this section.

Struct constructors have the following form:

```plaintext
type_name { [field_initializer,]... }
```

where each field_initializer has the form:

```plaintext
[field_name]=exp
```

Note how each field has an optional name field_name and a value exp. The expression for the value can be of any type. For convenience, a trailing comma is accepted but not required.

Suppose for example that we have a type defined as:

```plaintext
type Packet =
  struct
    { 
      uint<16> flags;
      byte[32] data;
    }
}
```

We can construct a new packet, with all its fields initialized to zero, like this:

```plaintext
(Poke) Packet {} 
Packet {
  flags=0x0UH,
  data=[0x0UB,0x0UB,0x0UB,0x0UB,0x0UB,...]
}
```

In the constructor we can specify initial values for some of the fields:

```plaintext
(Poke) Packet { flags = 0x8 }
Packet {
  flags=0x8UH,
  data=[0x0UB,0x0UB,0x0UB,0x0UB,0x0UB,...]
}
```

It is not allowed to specify initializers that are not part of the type being constructed:

```plaintext
(Poke) Packet { foo = 10 }
<stdin>:1:10: error: invalid struct field `foo' in constructor
Packet { foo = 10 };
```

As we shall see later, many struct types define constraints on the values their fields can hold. This is a way to implement data integrity. While building struct values using constructors, these constraints are taken into account. For example, given the following struct type:

```plaintext
type BPF_Reg =
  struct 
    { 
      uint<4> code : code < 11;
    }

```
we will get a constraint violation exception if we try to construct an BPF_Reg:

```
(poke) BPF_Reg { code = 20 }
unhandled constraint violation exception
```

### 25.6.3 Struct Comparison

The equality operator (==) and the inequality operator (!=) can be applied to struct values. Examples:

```
(poke) E_eof == E_eof
1
(Poke) Packet { payload=0x3 } != Packet { payload=0x4 }
1
```

The struct values are compared recursively.

### 25.6.4 Field Endianness

By default fields are accessed in IO space using the current default endianness. However, it is possible to annotate fields with an explicit endianness, like in:

```go
type Foo =
struct
{
  little int a;
  big int b;
  int c;
};
```

In the example above, the field a will be stored using little-endian, the field b will be stored using big-endian, and the field c will be stored using whatever current endianness.

The endianness annotations can be used in any kind of fields, like offsets, arrays and structs, and will impact the storage of integral fields defined in them.

When endianness annotations are used in struct fields which are themselves structs, they effectively change the default endianness in the contained struct. Therefore, in the following struct type:

```go
type Bar =
struct
{
  little struct
  {
    big int a;
    int b;
  } f;
  int c;
};
```

a is big endian, but b is little endian.

However, note that the scope of the big and little annotations is lexical. Therefore, in these types:

```go
type Foo =
struct
{
  int a;
  int b;
```
The endianness of the \texttt{a} and \texttt{b} fields stored in \texttt{f} is the default endianness, not \texttt{big}.

### 25.6.5 Accessing Fields

Poke uses the usual dot-notation to provide access to struct fields. Examples:

```poke
(poke) var s = struct { i = 10, l = 20L }
(poke) s.i
10
(poke) s.l
20L
```

Writing to fields is achieved by having the field reference in the left side of an assignment statement:

```poke
(poke) s.i = 100
(poke) s.l = 200
(poke) s
struct {i=100,l=200L}
```

### 25.6.6 Field Constraints

It is common for struct fields to be constrained to their values to satisfy some conditions. Obvious examples are magic numbers, and specification-derived constraints.

In Poke you can specify a field’s constraint using the following syntax:

```text
field_type field_name : expression ;
```

where \texttt{expression} is an arbitrary Poke expression, that should evaluate to an integer value. The result is interpreted as a boolean. As an example, this is how the ELF magic number is checked for:

```go
type Ctf_Preamble =
struct {
    uint<16> ctp_magic : ctp_magic == CTF_MAGIC;
    byte ctp_version;
    byte ctp_flags;
};
```

The constraint expression will often include the field where it is installed, but that’s not mandatory.

Field constraints play an important role in mapping. On one side, a map will fail if there is some constraint that fails. On the other, they guide the mapping of unbounded arrays. See Section 25.16.5 [Mapping Arrays], page 184.

Another common usage of constraint expressions is to alter the global state after decoding a field. For example, this is how mapping an ELF header sets the current endianness, depending on the value of \texttt{ei_data}:

```go
byte ei_data : ei_data == ELFDATA2LSB \ 
? set_endian (ENDIAN_LITTLE) \ 
```
Chapter 25: The Poke Language

: set_endian (ENDIAN_BIG);

Note that set_endian always returns 1.

25.6.7 Field Initializers

We saw that field constraints are useful to express magic numbers, which are pretty common in binary formats. Imagine a package has a marker byte at the beginning, which should always be 0xff. We could use a constraint like in:

```go
type Packet =
  struct {
    byte marker : marker == 0xff;
    byte length;
    byte[length] payload;
  };
```

This works well when mapping packages. The constraint is checked and a constraint violation exception is raised if the first byte of the alleged package is not 0xff.

However, suppose we want to construct a new Package, with no particular contents. We would use a constructor, but unfortunately:

```go
(poke) Packet { }
```

unhandled constraint violation exception

What happened? Since we didn’t specify a value for the marker in the struct constructor, a default value was used. The default value for an integral type is zero, which violates the constraint associated with the field. Therefore, we would need to remember to specify the marker, every time we construct a new packet:

```go
(poke) Packet { marker = 0xff }
```

```go
Packet {
  marker=0xffUB,
  length=0x0UB,
  payload=[]
}
```

Unfortunately, such markers and magic numbers are not precisely very memorable. To help with this, Poke has the notion of type field initializers. Let’s use one in our example:

```go
type Packet =
  struct {
    byte marker = 0xff;
    byte length;
    byte[length] payload;
  };
```

Note how the syntax is different than the one used for constraints. When a field in a struct type has an initializer, the struct constructor will use the initializer expression as the initial value for the field. For example:

```go
(poke) Packet {}
```

```go
Packet {
  marker=0xffUB,
  length=0x0UB,
  payload=[]
}
```
It is possible to specify both a constraint and an initializer in the same field. Suppose we want to support several kinds of packets, characterized by several markers. The supported markers are however a closed set. We could do it like this:

```go
type Packet =
  struct
  {
    byte marker = 0xff : marker in [0xffUB, 0xfeUB];
    byte length;
    byte[length] payload;
  };
```

Note however that struct mappers do not make use of field initializers, since the mapped IO space provides values for all the fields in the struct type. If we mapped the `Packet` type above, we would need to add also a constraint to make sure the value of `marker` is the right one. This also applies to constructing `Packet` types where an initial value is explicitly specified. We could do it by specifying both an initial value, and a constraint expression:

```go
type Packet =
  struct
  {
    byte marker = 0xff : marker == 0xff;
    byte length;
    byte[length] payload;
  };
```

This idiom is to common that Poke provides a more compact syntax to denote it, that avoids verbosity and replicated logic:

```go
type Packet =
  struct
  {
    byte marker == 0xff;
    byte length;
    byte[length] payload;
  };
```

It is considered good practice to design struct types in a way that a constructor with no arguments will result in something usable.

### 25.6.8 Field Labels

In structs, each field is associated with an offset, which is relative to the beginning of the struct. This is the offset used when reading and writing the field from/to the IO space when mapping.

The offset is reset to zero bits at the beginning of the struct type, and it is increased by the size of the fields:

```go
struct
{
  /* Offset: 0#b */
  uint<1> f1; /* Offset: 1#b */
  sint<7> f2; /* Offset: 1#B */
  int f3; /* Offset: 5#B */
  Bar f4; /* Offset: 23#B */
}
```

It is possible to specify an alternative offset for a field using a `field label`, using the following syntax:

```go
field_type field_name @ offset;
```
Which defines a label for the field `field_name` with value `offset`. Note that the label specifier shall appear after any constraint expression and initialization value if the field has these.

Consider for example an entry in an ELF symbol table. Each entry has a `st_info` field which is 64-bits long, that in turn can be interpreted as two fields `st_bind` and `st_type`.

The obvious solution is to encode `st_info` as a sub-struct that is integral, like this:

```c
struct {
    elf32_word st_name;
    struct uint<64>
    {
        uint<60> st_bind;
        uint<4> st_type;
    } st_info;
}
```

This makes the value of `st_info` easily accessible as an integral value. But we may prefer to use labels instead:

```c
struct {
    elf32_word st_name;
    elf64_word st_info;
    uint<60> st_bind @ 4#B;
    uint<4> st_type @ 4#B + 60#b;
}
```

The resulting struct has fields `st_info`, `st_bind` and `st_type`, with the last two overlapping the first.

Field labels are also useful in the rare cases where a variable part of a struct depends on some data that comes after it. This happens for example in the COFF “line number” structures, which are defined like this in C:

```c
struct external_lineno
{
    union
    {
        char l_symndx[4]; /* function name symbol index, iff l_lnno == 0*/
        char l_paddr[4]; /* (physical) address of line number */
    } l_addr;

    char l_lnno[L_LNNO_SIZE]; /* line number */
};
```

*i.e.* the `l_addr` field is to be interpreted as an index in a table or as a physical address depending on the value of `l_lnno`.

This is one way to denote the above data structure using Poke struct labels:

```c
type COFF_LINENO_32 =
struct
{
    uint<32> l_lnno 4#B; /* Line number. */

    union
    {
        uint<32> l_symndx : l_lnno == 0;
    }
};
```
Note how the l_lnno field is stored after l_addr even if they appear in reverse order in the struct definition. This allows us to refer to l_lnno in the constraints for the union fields.

### 25.6.9 Pinned Structs

Pinned structs is a convenient way to write struct types where the offset of all its fields is zero. They are equivalent to C unions.

For example, consider the _u field below in a CTF type description:

```c
    type Ctf_Stype_V1 =
    struct
        Ctf_Name ctt_name;
        Ctf_Info_V1 ctt_info;
        pinned struct
            { uint32 _size; /* Size of entire type in bytes. */
            uint32 _type; /* Reference to another type. */
        } _u;
    };
```

Note that integral structs cannot be pinned. See Section 25.6.11 [Integral Structs], page 155. And field labels are not allowed in pinned structs.

### 25.6.10 The OFFSET variable

The offset of the current field being mapped or constructed, relative to the beginning of the struct, is at all times available in a variable called OFFSET. This is useful in situations where we need that information in a constraint expression, the boundary of an array, an initialization value, or the like.

For example, what follows is a typical usage of OFFSET in order to introduce some padding in a struct:

```c
    type Elf64_Note =
    struct
        { [...] 

        Elf64_Xword name;
        byte[aligns to (OFFSET, 4#B)] padding;

        [...] 
    };
```

The value of this variable changes every time a new field is mapped or constructed, so writing to it will only have effect until the next field is processed: at that time the value will be overwritten.

### 25.6.11 Integral Structs

Integral structs are useful to cover cases where data is stored in composited integral containers, *i.e.* where data is structured within stored integers.
Basically, when we structure data using Poke structs, arrays and the like, we often use the same structure than a C programmer would use. For example, to model ELF RELA structures, which are defined in C like:

```c
type struct
{
    Elf64_Addr r_offset; /* Address */
    Elf64_Xword r_info; /* Relocation type and symbol index */
    Elf64_Sxword r_addend; /* Addend */
} Elf64_Rela;
```

we could use something like this in Poke:

```pke
type Elf64_Rela =
struct
{
    Elf64_Addr r_offset;
    Elf64_Xword r_info;
    Elf64_Sxword r_addend;
};
```

Here the Poke struct type is pretty equivalent to the C incarnation. In both cases the fields are always stored in the given order, regardless of endianness or any other consideration.

However, there are situations where stored integral values are to be interpreted as composite data. This is the case of the `r_info` field above, which is a 64-bit unsigned integer (`Elf64_Xword`) which is itself composed by several fields, depicted here:

```
+----------------------+----------------------+
| r_sym | r_type |
+----------------------+----------------------+
```

In order to support this kind of composition of integers, C programmers usually resort to either bit masking (most often) or to the often obscure and undefined behaviour-prone C bit fields. In the case of ELF, the GNU implementations define a few macros to access these sub-fields:

```c
#define ELF64_R_SYM(i) ((i) >> 32)
#define ELF64_R_TYPE(i) ((i) & 0xffffffff)
#define ELF64_R_INFO(sym,type) ((((Elf64_Xword) (sym)) << 32) + (type))
```

Where `ELF64_R_SYM` and `ELF64_R_TYPE` are used to extract the fields from an `r_info`, and `ELF64_R_INFO` is used to compose it. This is typical of C data structures.

We could of course mimic the C implementation in Poke:

```pke
fun Elf64_R_Sym = (Elf64_Xword i) uint<32>:
{ return i .>> 32; }

fun Elf64_R_Type = (Elf64_Xword i) uint<32>:
{ return i & 0xffffffff; }

fun Elf64_R_Info = (uint<32> sym, uint<32> type) Elf64_Xword:
{ return sym as Elf64_Xword << . 32 + type; }
```

However, this approach has a huge disadvantage: since we are not able to encode the logic of these "sub-fields" in proper Poke fields, they become second class citizens, with all that implies: no constraints on their own, can’t be auto-completed, can’t be assigned individually, etc.

This is where integral structs come to play. These are structs that are defined exactly like your garden variety Poke structs, with a small addition:

```pke
type Elf64_RelInfo =
```
struct uint<64>
{
    uint<32> r_sym;
    uint<32> r_type;
};

Note the uint<64> addition after struct. This can be any integer type (signed or unsigned). The fields of an integral struct should be integral themselves (this includes both integers and offsets) and the total size occupied by the fields should be the same size than the one declared in the struct’s integer type. This is checked and enforced by the compiler.

It is also possible to not specify the overall size of the integral struct and let it be deduced from the sizes of the struct fields. To do so, use the int<*> and uint<*> type specifiers. In this example:

type Elf64_RelInfo =
    struct uint<*>
    {
        uint<32> r_sym;
        uint<32> r_type;
    };

If you don’t specify an explicit size for the integral struct, the compiler will make sure that the sum of the sizes of the fields is within the proper range for the number of bits of a signed or unsigned integral type, whatever applies, emitting an error in case it is out of range (like for example a size of only one bit for a signed integral struct, or a size exceeding 64 bits.)

The Elf64 RELA in Poke can then be encoded like:

type Elf64_Rela =
    struct
    {
        Elf64_Addr r_offset;
        struct Elf64_Xword
        {
            uint<32> r_sym;
            uint<32> r_type;
        } r_info;
        Elf64_Sxword r_addend;
    };

When an integral struct is mapped from some IO space, the total number of bytes occupied by the struct is read as a single integer value, and then the values of the fields are extracted from it. A similar process is using when writing. That is what makes it different with respect a normal Poke struct.

Consider for example we have the following sequence of bytes in our IO space (like a file):
0x10 0x20 0x30 0x40 0x50 0x60 0x70 0x80

Let’s see what happens when we map the integral struct above, in both big and little endian:
(poke) .set endian big
(poke) Elf64_RelInfo @ 0#B
Elf64_RelInfo {
    r_sym=0x10203040U,
    r_type=0x50607080U
}
(poke) .set endian little
(poke) Elf64_RelInfo @ 0#B
Elf64_RelInfo {
    r_sym=0x80706050U,
    r_type=0x40302010U
}

Looks good. For comparison, this is what happens when we do the same with an "equivalent" (not really) non-integral struct operating on the same data:

type Elf64_RelInfoBogus =
    struct
    {
        uint<32> r_sym;
        uint<32> r_type;
    };

We would get:

(poke) .set endian big
(poke) Elf64_RelInfoBogus @ 0#B
Elf64_RelInfoBogus {
    r_sym=0x10203040U,
    r_type=0x50607080U
}

(poke) .set endian little
(poke) Elf64_RelInfoBogus @ 0#B
Elf64_RelInfoBogus {
    r_sym=0x40302010U,
    r_type=0x80706050U
}

In this case, and unlike with integral structs, the endianness impacts the bytes of the individual fields, not of the whole struct.

As you can see, integral structs can be used to denote a lot of commonly found idioms in data structures and this includes a lot of what is sometimes denoted in C bit field. However, one should be cautious when "translating" C structures to Poke, especially when the C programmer has not been careful and incurs in sometimes obscure implementation-defined behavior. An integral struct is not always the right abstraction to use when we see a C bit field!

As an example of the above, consider the following C struct:

```c
struct regs 
{
    __u8 dst_reg:4;
    __u8 src_reg:4;
};
```

Certain virtual architecture uses that data layout to store registers in instructions (no comment.) Thing is, in bit fields like the above with sub-byte field sizes, the ordering of the fields is not clearly defined, and ultimately what order to use is up to the compiler, i.e. to lore and tradition. As it happens, GCC encodes src_reg in the most significant nibble of the byte and dst_reg in the least significant nibble of the byte when compiling for a little-endian target, and the other way around when compiling for a big-endian target. (I may have had that wrong, this always confuses me.)

How could we encode the C struct regs in Poke? Let’s see.

A normal Poke struct clearly won’t do it:

```c
type RegsBogus1 =
    struct
```

The reason being, the ordering of src and dst does not change when you switch endianness (since this is Poke, we can in fact talk about real ordering of bits)... remember, poke is WYPIWIG (what you poke is what you get) ;)

What about an integral struct?

```go
type RegsBogus2 =
  struct uint<8>
  {
    uint<4> src;
    uint<4> dst;
  };
```

This won’t work either. In fact, the net effect of the normal decoding of the normal struct type RegsBogus1 and the map-an-integer-and-extract-fields decoding of the integral struct RegsBogus2 is in this case totally equivalent.

A solution is to use a normal struct, and field labels:

```go
type RegsBogus =
  struct
  {
    var little_p = (get_endian == ENDIAN_LITTLE);
    uint<8> src @ !little_p * 4#b;
    uint<8> dst @ little_p * 4#b;
  };
```

At this point, you may be wondering: is there anything particular in a field defined in an integral struct? The answer is: no, not at all. These are regular, first-class fields. Likewise, integral structs are perfectly regular structs. And of course, since this is poke, you can have integral structs of say, 11 bits, or 3 bits, map them at offsets not aligned to bytes, and all the typical poke-atrocities that we enjoy so much.

However, there exist a few restrictions, some of them fundamental, the others to be lifted eventually:

- Integral structs can only have integral fields. This includes offsets and integral structs.
- No labels are allowed in the fields of integral structs. This is not a fundamental limitation, and may be supported at some point.
- No optional fields are supported in integral structs. Support for this is actually partially implemented (the mapper supports them but not the writer) and most probably will be completed one of these days.

Integral structs can be converted from/to integral structs to/from integers, so we can do things like:

```go
rel.r_info as uint<64>;
```

And also automatic promotions in arithmetic operators, like:

```go
rel.r_info + 20 * rel.r_info.r_type
```

Integers can also be “structured” into integral structs:

```go
(poke) 0xdeadbeef as Elf32_RelInfo
Elf32_RelInfo {
    r_sym=(uint<24>) 0xdeadbe,
```
25.6.12 Unions

Union types are defined much like struct types, using a very similar syntax:

```plaintext
union {
    [... elements ...]
}
```

Like in structs, the main kind of elements are fields. However, unlike in structs, the fields in an union type denote alternatives. At any given time, only one alternative is selected, and therefore union values have only one field.

Which of the several alternatives is selected is determined by the data integrity defined by means of constraint expressions and other means. Alternatives are considered in turn, in written order, and the first alternative that can be used without triggering a constraint violation exception is selected.

It makes little sense to mark union types as pinned, since whatever alternative is chosen will always be located at the beginning of the union. To avoid unnecessary confusion, the Poke compiler will emit an error if you try to tag an union as pinned.

Similarly, labels are not allowed in union alternatives.

25.6.13 Union Constructors

Constructing union values is very similar to constructing struct values:

```plaintext
type_name { [field_initializer] }
```

The main difference is that union constructors require either exactly one field initializer, or none. Specifying initialization values for more than one field doesn’t make sense in the case of unions.

Suppose we have the following union type:

```plaintext
type Packet =
    union {
        byte b : b > 0;
        int k;
    }
```

If we try to construct a `Packet` with an invalid `b`, we get a constraint error:

```plaintext
(poke) Packet {b = 0}
unhandled constraint violation exception
```

The reason why `k` is not chosen is because we specified `b` in the union constructor: we explicitly as for a `Packet` of that kind, but the data we provide doesn’t accommodate to that. If we wanted another kind of value, we could of course specify an initial value for `k` instead:

```plaintext
(poke) Packet {k = 10}
Packet {k=10}
```

If no field initializer is specified in an union constructor then each alternative is tried assuming all fields have default values, which in the case of integral types is a zero:

```plaintext
(poke) Packet {} 
Packet {
```
Therefore the alternative b is considered invalid (it has to be bigger than 0) and k is chosen instead.

25.6.14 Integral Unions

Integral unions are useful to cover cases where we have variants of data encoded in integers. One example could be CPU instructions encoded as 16-bit or 32-bit numbers.

```pokelang
type InstructionFormat_1 =
  struct uint<32>
  {
    uint<20> imm31_12;
    uint<5>   rd;
    uint<7>   opcode : valid_opcode_for_format_1 (opcode);
  };

type InstructionFormat_2 =
  struct uint<32>
  {
    uint<7> funct7;
    uint<5>  rs2;
    uint<5>  rs1;
    uint<3>  funct3;
    uint<5>   rd;
    uint<7>   opcode : valid_opcode_for_format_2 (opcode);
  };

type Instruction =
  union uint<32>
  {
    InstructionFormat_1 f1;
    InstructionFormat_2 f2;
  };
```

Like integral structs, integral unions can be casted to/from integers; e.g., \(3211411U\) as Instruction will create an Instruction union.

Like integral structs, integral unions can have fields of the following types: integral, offset, integral struct or union.

25.6.15 Optional Fields

Sometimes a field in a struct is optional, i.e. it exists or not depending on some criteria. A good example of this is the “extended header” in a MP3 id3v2 tag. From the specification:

The second bit (bit 6) indicates whether or not the header is followed by an extended header. The extended header is described in section 3.2. A set bit indicates the presence of an extended header.

In order to express this in a Poke struct type, we could of course use an union, like:

```pokelang
type ID3V2_Tag =
  struct
  {
    ID3V2_Hdr hdr;
    union
  };
```
That’s it, we use an union with an empty alternative. However, this approach has two problems. First, it is a bit cumbersome to write and it becomes necessary to introduce an intermediate named field like ext above. Second, and most importantly, the constraint expression in the union alternative is evaluated only once the alternative has been already decoded.

Therefore Poke provides a more convenient way to denote this:

```go
type ID3V2_Tag =
  struct
  { ID3V2_Hdr hdr;
    if (hdr.extended_hdr_present) IDV2_Ext_Hdr ext_hdr;
    ...
  } ext;
...
```  

In the example above ext_hdr will be decoded only if hdr.extended_hdr_present is true, which is what we want.

Sometimes, however, we really need to decode a field to decide whether it is present or absent in the final struct. In these cases, we can use a suffix syntax:

```go
type ID3V2_Tag =
  struct
  { ID3V2_Hdr hdr;
    IDV2_Ext_Hdr ext_hdr if hdr.extended_hdr_present && ext_hdr.invisible;
    ...
  }
```  

Note how in this example the field ext_hdr can appear itself in the conditional expression.

If both a constraint and a suffix optional field expression are specified, the second should follow the first.

One important characteristic of optional fields with suffix expressions to keep in mind is that they are always constructed or mapped, even when they are omitted. This is because, generally speaking, the value of an optional field may be necessary in order to determine whether the optional field is present or not.

This may result on unexpected results for the unaware pokist, like in the example below:

```go
struct
{ Header hdr;
  byte[hdr.len - hdr.padding] data if hdr.len >= hdr.padding;
}
```  

where the array index may underflow if hdr.len is less or equal than hdr.padding.

The obvious solution for this problem is to use a prefix conditional expression instead.

For obvious reasons, optional fields are not allowed in unions.
25.6.16 Casting Structs

It is possible to cast a struct of some particular type into another struct type (but not to an union.) Examples:

(poke) type Foo = struct { int i; int j; }
(poke) type Bar = struct { int k; int j; }
(poke) Bar {j=2} as Foo {}
  Foo {i=0,j=2}

The semantics of the cast are exactly the same than constructing a struct of the target type using the struct provided as an expression to the cast.

This means that some fields in the original struct may be “lost” when the struct is converted to the new type. Consider the following two definitions:

type Foo = struct { int i; long j; }
type Bar = struct { int i; }

Let’s cast some values and see what we obtain:

(poke) Bar {}
Bar {
  i=0x0
}
(poke) Bar {} as Foo
Foo {
  i=0x0,
  j=0x0L
}
(poke) Foo {} as Bar
Bar {
  i=0x0
}

It is possible to cast an integral struct into an integral type. The value to cast is extracted from the struct fields, and then it is converted to the target type.

Given the following integral struct type:

type Foo =
  struct int<64>
    {
      int<32> f1;
      uint<32> f2;
    }
;

We can operate:

(poke) Foo { f1 = 1, f2 = 1 } as uint<64> + 2
  0x100000003UL

Conversely, it is possible to cast an integral value to an integral struct:

(poke) 0x100000003UL as Foo
Foo {
  f1=0x1,
  f2=0x3U
}
25.6.17 Declarations in Structs

Type declarations, variable declarations and function declarations are all allowed inside struct and union types. The scope of the entity being declared spans from the declaration until the end of the struct or union type being defined.

Functions can’t set fields defined in the struct type.

25.6.18 Methods

Methods in structs can be defined using the method keyword in definitions like this:

```
method identifier = function_body
```

where `function_body` is the body of a function. See Section 25.13.1 [Function Declarations], page 173.

When invoked, a method gets an implicit last argument which is the struct value whose method is being used.

Methods can refer to the fields of the containing struct type that have been defined before the method itself, by name.

Additionally, the containing struct can be referred explicitly under the name SELF in the body of the method. SELF has type any.

25.6.19 Struct Pretty Printers

By default the printing statements will print a very detailed written representation of struct and union values. This implies printing out every detail of every field.

However, it is possible to change the written representation of a struct value by defining pretty-printing methods, which have prototypes:

```
method _print = void: { method_body }
```

If a struct or union type has a method called _print, then it is invoked every time a printed representation of the value shall be printed on the terminal.

For example a value of a struct type:

```
type Switch =
  struct{
    int<32> state;

    method _print = void:
      {printf "#<switch:%i32d>", state;}
  };
```

When printed when pretty-printers are active, will result in:

```
(poke) .set pretty-print yes
(poke) Switch { state = 1 }
#<switch:1>
```

Struct or union fields can also have pretty-printers defined for them: just define a method called _print_field_name to pretty-print a particular field.

For example a value of a struct type:

```
type Switch =
  struct{
    int<32> state;
```
method _print_state = void:
{
    printf ("#<%s>", state ? "on" : "off");
}
};

This will result in:

(poke) .set pretty-print yes
(poke) Switch { state = 1 }
Switch {
    state=#<on>
}

25.6.20 Computed Fields

A computed field declaration in a struct or union type has the form:

computed field_type field_name;

Where field_type is a type specifier denoting the type of the computed field, and field_name is an identifier. Note that, unlike regular fields, computed fields cannot have endianness annotations, constraints defined for them, cannot be optional, nor have initialization values.

Computed fields are not really stored in the corresponding struct values: their value is computed every time they are referred, by invoking a couple of methods that the user should define:

− A getter method with name get_field_name and signature ()field_type.
  This getter is used to compute the value of the computed field when it is referenced as a r-value.

− A setter method with name set_field_name and signature (field_type)void.
  This setter is called when the computed field is assigned to in a l-value.

For example, consider the following struct denoting a RISC-V instruction where the immediate is distributed in several chunks:

```r

type RV32InsnFmt_J = struct uint<32>
    {
        uint<1> imm20;
        uint<10> imm10_1;
        uint<1> imm11;
        uint<8> imm19_12;
        RV_Reg rd;
        RV_Opcode opcode : opcode in RV_OPCODES_J;
        computed int<32> imm;
    }

method get_imm = int<32>:
{
    return imm20:::imm19_12:::imm11:::imm10_1:::(0 as int<1>) as int<21>;
}

method set_imm = (int<32> imm) void:
{
    imm20 = (imm .>> 20) & 1;
    imm10_1 = (imm .>> 19) & 0x3ff;
```
imm11 = (imm .>> 10) & 1;
imm19_12 = (imm .>> 19) & 0xff;
}
};

When we create a value of type RV32_InsnFmt_J we can then externally access the computed field imm like any other normal field. However, computed fields are not accessible in other struct methods, functions, constraint expressions and the like.

### 25.6.21 Struct Attributes

The following attributes are defined for struct values.

- **size**
  
  Gives an offset with the storage occupied by the complete struct. Example:
  
  ```
  (poke) type Packet = struct { byte s; byte[s] d; }
  (poke) (Packet { s = 3 })'size
  32UL#b
  ```

- **length**
  
  Gives the number of fields stored in the struct. Note that, due to absent fields, this doesn’t always correspond to the number of fields that appear in the definition of a struct type.
  
  For example, for the following struct type:
  
  ```
  type Packet =
  struct
  { byte magic: magic in [0xffUB,0xfeUB];
    byte control if magic == 0xfe;
    byte[128] payload;
  };
  ```
  
  We get the following results:
  
  ```
  (poke) (Packet { magic = 0xff })'length
  2UL
  (poke) (Packet { magic = 0xfe })'length
  3UL
  ```

- **mapped**
  
  Boolean indicating whether the struct is mapped.

- **strict**
  
  Boolean indicating whether the struct is mapped in strict mode.

- **elem (idx)**
  
  Element occupying the position idx in the array. Note that this attribute evaluates to a value of type any.

- **eoffset (idx)**
  
  Offset of the field identified by the index idx in the struct. Examples:
  
  ```
  (poke) type Foo = struct { int i; long l; }
  (poke) Foo{}'eoffset (1)
  32#b
  ```
  
  If the provided index is out of bounds then E_out_of_bounds is raised.

- **esize (idx)**
  
  Size of the field identified by the index idx in the struct. Examples:
  
  ```
  (poke) type Foo = struct { int i; long l; }
  (poke) Foo{}'esize (1)
  64#b
  ```
  
  If the provided index is out of bounds then E_out_of_bounds is raised.
ename (idx)
  Name of the field identified by the index idx in the struct. If the field is anonymous then the empty string.
  Examples:
  
  (poke) type Foo = struct { int foo; long bar; }  
  (poke) Foo{}'ename (0)  
  "foo"
  If the provided index is out of bounds then E_out_of_bounds is raised.

25.7 Types

25.7.1 type
  The type directive allows you to declare named types. The syntax is:

  type name = type [ , name = type]...;

  where name is the name of the new type, and type is either a type specifier or the name of some other type.

  The supported type specifiers are:

  int<n>, uint<n>
  Integral types. See Section 25.2.4 [Integer Types], page 132.

  string
  The string type. See Section 25.4.2 [String Types], page 140.

  type[boundary]
  Array types. See Section 25.5.2 [Array Types], page 142.

  struct { ... }
  Struct types. See Section 25.6.1 [Struct Types], page 148.

  (type,...)type:
  Function types. See Section 25.13.5 [Function Types], page 174.

  any
  The any type is used to implement polymorphism. See Section 25.7.2 [The any Type], page 167.

25.7.2 The any Type
  Poke supports polymorphism with the any type. This type is used in contexts where a value of any type is allowed. For example, this is how you would declare a function that prints the size of any given value:

  fun print_size = (any value) void:
  {  
    printf "%v\n", any'size;
  }

  The rules for handling any values are simple:
  − Everything coerces to any.
  − Nothing coerces from any.

  This means that using any operator that require certain types with any values will fail: you have to cast them first. Example:

  (poke) fun foo = (any v) int: { return v as int; }

  Arrays of any, any [], are also supported.

  Values of type any can be compared for equality and inequality, using the == and != operators.
25.7.3 The isa Operator

The binary operator isa allows you to check for the type of a given value:

- (poke) 10 isa int
- (poke) "foo" isa string
- (poke) (Packet 0#B) isa Packet
- (poke) 2 as int<3> isa uint<4>

25.7.4 typeof

The typeof language construction provides information about some Poke type. It has the form:

typeof (entity)

where entity is either a value or a type specifier. It returns a Pk_Type value describing either the specified type, or the type of the specified value.

The Pk_Type struct provides the following fields for all kind of types:

- **uint<32> code**
  - This is a numerical code that identifies the kind of the described type.
  - Valid codes are PK_TYPE_UNKNOWN, PK_TYPE_INTEGRAL, PK_TYPE_OFFSET, PK_TYPE_STRING, PK_TYPE_ARRAY, PK_TYPE_STRUCT, PK_TYPE_FUNCTION and PK_TYPE_ANY.

- **string name**
  - If the described type is named, then this field contains the name. Otherwise it is the empty string.

- **int<32> complete_p**
  - If the size of the described type can be determined at compile time, then this field is 1, 0 otherwise.

  The following fields are provided in Pk_Type only for integral, offset and integral struct types:

- **int<32> signed_p**
  - If the described type is signed, this field is 1, 0 otherwise.

- **uint<64> size**
  - The number of bits of values of the described integral type, or the number of bits of the integral value of the described integral struct type, or the number of bits of the magnitude of the described offset type.
  - This would be 23UL for an int<23> type, and 32UL for an offset<int<32>,1> type.

  The following fields are provided in Pk_Type only for offset types:

- **_unit**
  - The unit of the described offset type, in bit units. This would be 8UL for an offset<int<32>,B> type, for example.
The following fields are provided in \texttt{Pk\_Type} only for array types:

\begin{verbatim}
\hat{\text{int<32>}} \text{ bounded\_p}
\end{verbatim}
This field is 1 if the described array type is bounded by either number of elements or by size, 0 otherwise.

The following fields are provided in \texttt{Pk\_Type} only for struct types:

\begin{verbatim}
\hat{\text{int<32>}} \text{ union\_p}
\end{verbatim}
This field is 1 if the described struct type is an union, 0 otherwise.

\begin{verbatim}
\hat{\text{int<32>}} \text{ pinned\_p}
\end{verbatim}
This field is 1 if the described struct type is pinned, 0 otherwise.

\begin{verbatim}
\hat{\text{int<32>}} \text{ integral\_p}
\end{verbatim}
This field is 1 if the described struct type is integral, 0 otherwise.

\begin{verbatim}
\text{int<32>} \text{ nfields}
\end{verbatim}
Number of fields defined in the described struct type. This count includes optional fields and computed fields.

\begin{verbatim}
\text{int<32>} \text{ nmmethods}
\end{verbatim}
Number of methods defined in the described struct type.

\begin{verbatim}
\text{string[]} \text{ fnames}
\end{verbatim}
Array of \text{nfields} strings, with the names of the fields defined in the described struct type. Anonymous fields feature empty strings.

\begin{verbatim}
\text{int<32>[]} \text{ fcomputed}
\end{verbatim}
Array of \text{nfields} integers, which are 1 for fields that are computed, 0 for fields that are not computed.

\begin{verbatim}
\text{string[]} \text{ ftypes}
\end{verbatim}
Array of \text{nfields} strings, with the type specifiers of the types of the fields defined in the described struct type.

\begin{verbatim}
\text{string[]} \text{ mnames}
\end{verbatim}
Array of \text{nmmethods} strings, with the names of the methods defined in the described struct type.

\begin{verbatim}
\text{string[]} \text{ mtypes}
\end{verbatim}
Array of \text{nmmethods} strings, with the type specifiers of the types of the methods defined in the described struct type.

\begin{verbatim}
\text{(any)any deintegrator}
\end{verbatim}
Closure that, when passed an integral value of the same signedness and width than the described integral struct, returns the struct value corresponding to that value.

\begin{verbatim}
(poke) \text{type Foo = struct} \text{int<32> { int<16> a; uint<16> b; }}
(poke) \text{typeof (Foo).deintegrator (0x0eadbeef)}
\end{verbatim}
\begin{verbatim}
Foo {
  a=0x0eadH,
  b=0xbeefUH
}
\end{verbatim}

The following fields are provided in \texttt{Pk\_Type} only for struct and array types:

\begin{verbatim}
\text{(int<32>,int<32>,uint<64>)any mapper}
\end{verbatim}
Closure that, when passed an integer predicate denoting whether to do a strict mapping, an IO space identifier, a bit-offset in the given IO space, map a value of the described type.
(any)void writer
Closure that, when passed a mapped value of the described type, writes the contents of the value to the corresponding IO space.

(any)any integrator
Closure that, when passed a value of the described type (an array type or an integral struct type) returns the integral value corresponding to the contents of the value.

```go
(type Foo = struct int<32> { int<16> a; uint<16> b; } (poke) typeof (Foo).integrator (Foo { a = 0xab, b = 0xcd }) 0x00ab00cd
```

(any,any)int<32> comparator
Closure that, when passed two values of the described type, returns 1 if the values are equal, 0 otherwise.

### 25.8 Assignments

#### 25.8.1 Simple Assignments

The assignment statement has the form:

```
lvalue = exp;
```

where `lvalue` is either:

- A variable.
- A field reference like `foo.bar`.
- A map of a type, like `int @ 0#B` or `int[3] @ 0#B` or `Packet @ 12#B`.

In all cases, the type of `exp` should match the type of the referred entity.

Examples:

```go
(poke) foo = 10
(poke) packet.length = 4
(poke) packet.data = [1,2,3,4]
(poke) packet.data[2] = 666
(poke) int @ 23#B = 23
(poke) string @ str.offset = "foo"
(poke) int[2] @ 23#B = [1,2]
(poke) Packet @ 0#B = Packet { ... }
```

#### 25.8.2 Bit Assignments

*Bit assignment* statements have the form:

```
bconc_exp = exp
```

Where `bconc_exp` is an expression composed by bit-concatenation operators and operands that should be valid l-values themselves, and `exp` is an expression whose type must be integral and whose width must correspond exactly to the width of the integral type of `bconc_exp`.

For example, consider this code:

```go
var a = 0UH;
var b = 0UH;

a:::b = 0xbeef;
```

The assignment above updates the value of the variable `a` to be `0xbeUH` and the value of the variable `b` to be `0xefUH`. Note how the signedness of `bconc_exp` and `exp` may differ.
Any valid l-value can be used as an operand of the bit-concatenation operators in \texttt{bconc\_exp}. For example:

\begin{verbatim}
var a = [0UH,0UH];

a[0]:::a[1] = 0xbeef;
\end{verbatim}

or, using struct fields:

\begin{verbatim}
type Foo = struct { uint<16> hi; uint<16> lo; };

var f = Foo {};

f.hi:::f.lo = 0xbeef;
\end{verbatim}

### 25.9 Compound Statements

Compound statements have the form

\begin{verbatim}
{ stmt... }
\end{verbatim}

where \texttt{stmt...} is a list of statements, which can be themselves compound statements. Compound statements are primarily used to sequence instructions like:

\begin{verbatim}
{ do_a;
  do_b;
  do_c;
}
\end{verbatim}

A compound statement introduces a new lexical scope. Declarations in the compound statements are local to that statement.

Finally, compound statements can be empty: \begin{verbatim}\{\}\end{verbatim}.

### 25.10 Conditionals

Poke provides several conditional statements, and a ternary conditional operator, which are discussed in the sections below.

#### 25.10.1 if-else

The \texttt{if-else} statement has the form

\begin{verbatim}
if (exp) if\_stmt [else else\_stmt]
\end{verbatim}

where \texttt{exp} is an expression that should evaluate to a boolean value (\textit{i.e.} to an integer), \texttt{if\_stmt} is a statement that will be executed if \texttt{exp} holds true, and \texttt{else\_stmt} is a statement that will be executed if \texttt{exp} holds false. The \texttt{else} part of the statement is optional.

#### 25.10.2 Conditional Expressions

Poke supports a ternary conditional expression that has the form:

\begin{verbatim}
condition ? true\_expression : false\_expression
\end{verbatim}

where \texttt{condition} is an expression that should evaluate to a boolean, and \texttt{true\_expression} and \texttt{false\_expression} are expressions that have exactly the same type.

### 25.11 Loops

Poke supports several iteration statements, which are discussed in the sections below.
25.11.1 while
The **while** statement has this form:

```
while (exp) stmt
```

where `exp` is an expression that should evaluate to a boolean (i.e. to an integer) and `stmt` is a statement that will be executed until `exp` holds false.

It is possible to leave the loop from within `stmt` using the **break** statement. Example:

```
while (1)
{
  [...]
  if (exit_loop)
    break;
}
```

It is also possible to jump to the next iteration of the loop from within `stmt` using the **continue** statement. Example:

```
while (1)
{
  [...]
  if (continue_loop)
    continue;
}
```

25.11.2 for
The **for** statement has this form:

```
for ([decls];[expr];[stmts]) stmt
```

where `decls` is an optional declaration or chain of declarations separated by commas, `expr` is an optional boolean expression, `stmts` is an optional comma-separated list of statements, and `stmt` is a statement.

25.11.3 for-in
The **for-in** statement has this form:

```
for (formal in container [where exp]) stmt
```

where, in each iteration, the name `formal` will be associated with consecutive values of `container`, which shall be an expression evaluating to an array or a string. `formal` is available in `stmt`, which is the statement executed in each iteration.

If the **where** part is specified, then only iteration in which `exp` holds true are processed. `formal` can be referred in `exp`. Note that this doesn’t mean the loop will stop after processing the first “not selected” element. See the following example:

```
(poke) for (c in [1,2,3,4] where c % 2) printf " %v", c
  1 3
```

It is possible to leave the loop from within `stmt` using the **break** statement.

It is also possible to jump to the next iteration of the loop from within `stmt` using the **continue** statement.

25.12 Expression Statements
Poke is one of these languages where there is a clear separation between expressions and statements. However, it is often useful to use an expression in the place of an statement, in order to benefit from its side effects.
For that purpose Poke allows you to expressions as statements using the following syntax:

```pokelang
exp;
```

The value computed by the expression will be discarded.

### 25.13 Functions

#### 25.13.1 Function Declarations

A function is declared using the following syntax:

```pokelang
fun name = [(formal,...)] ret_type:
{
  ... body ...
}
```

where `name` is the name of the function, which uses the same namespace as variables and types and `ret_type` is the type of the value returned by the function. If the function returns no value then it is `void`.

Each `formal` argument has the form:

```pokelang
type name [= exp]
```

where `type` is the type of the formal, `name` its name, and `exp` is an optional expression that will be used to initialize the argument in case it is not specified when the function is called.

The last formal argument can take the form `name...`, meaning the function is variadic. See Section 25.13.3 [Variadic Functions], page 174.

If the function takes no arguments, it is possible to omit the list of arguments entirely:

```pokelang
fun hello = void: { print "Hello!\n"; }
```

The `return` statement is used to return values in functions that return a value. Example:

```pokelang
fun gcd = (uint<64> a, uint<64> b) uint<64>:
{
  if (b == 0)
    return a;
  else
    return gcd (b, a % b);
}
```

Note that reaching the end of a non-void function will trigger a run-time error.

#### 25.13.2 Optional Arguments

Optional function arguments are specified like:

```pokelang
fun atoi = (string s, int b = 10) long: { ... }
```

Which means that if the base argument is not specified when passed to `atoi` then it is initialized to 10.

Optional arguments should not appear before any non-optional argument in function declarations. The following is not valid Poke:

```pokelang
fun foo = (int i = 10, int j) int: { return i + j; }
```

Note that arguments declared before an optional argument can be used in its initialization expression. This is valid Poke:

```pokelang
fun foo = (int n, int[n] array = init_array (n)) void: { ... }
```
25.13.3 Variadic Functions
Functions getting an arbitrary number of arguments are denoted like this:

```pascal
fun printf (string fmt, args...) void: { ... }
```

The variadic argument shall be the last argument in the function, and it is of type `any[]`.

25.13.4 Calling Functions
To call a function, write its name followed by the arguments in parentheses. Examples:

```pascal
foo (1,2,3)
bar ()
```

If the function takes no arguments then it is not necessary to write the empty list of arguments. Therefore the following two calls are equivalent:

```pascal
bar ()
bar
```

If the closure of function that takes no arguments is needed, the call can be avoided by putting the variable immediately inside parenthesis, like this:

```pascal
(poke) (foo)
#<closure>
```

There is an alternate syntax that can be used in both expressions and expression-statements. This alternate syntax is:

```pascal
function_name :arg1 val1...
```

where `arg1` is the name of an argument and `val1` the value to pass for that argument. This is useful when using functions as commands in the REPL:

```pascal
(poke) dump :from 12#B :size 16#B :ascii 0
```

Note that the named arguments can appear in any order. The following two calls are equivalent:

```pascal
dump :from 12#B :size 16#B
dump :size 16#B :from 12#B
```

If this alternate syntax for function calls is to be used in an expression, it is necessary to surround it with parenthesis:

```pascal
2 + (gcd :a 1024 :b 8)
```

25.13.5 Function Types
Function types are denoted like:

```pascal
(type,...)ret_type:
```

where `type` are the types of the arguments and `ret_type` is the type of the value returned by the function.

Optional arguments are marked with a `?` after the type. For example, the type of the `atoi` function with declaration:

```pascal
fun atoi = (string s, int b = 10) long: { ... }
```

is `(string,int?)long:`.

If the function has variadic arguments, the position of the variadic argument in the function type specifier contains `...`. For example, the type of a `printf` function with declaration:

```pascal
fun printf (string fmt, args...) void: { ... }
```

is `(string,..)void:`.
25.13.6 Lambdas

Poke support **lambda expressions** using the following syntax:

```
lambda function_specifier
```

Where `function_specifier` is any function specifier. Examples:

```c
lambda void: {}  
lambda (int i) int: { return i * 2; }
```

Lambdas can be manipulated exactly like any other Poke value, and can be stored in variables. Therefore, this is an alternative way of defining a named function (which can’t be recursive for obvious reasons):

```
var double = lambda (int i) int: { return i * 2; }
```

25.13.7 Function Comparison

The equality operator (`==`) and the inequality operator (`!=`) can be applied to functions. They evaluate to true if the operands are the same function value. Examples:

```c
(poke) lambda void: {} == lambda void: {}  
0  
(poke) lambda void: {} != lambda void: {}  
1  
(poke) var f = void: {}  
(poke) f == f  
1  
(poke) f != f  
0
```

25.13.8 Function Attributes

The following attributes are defined for function values.

- **size**: Gives an offset 0#B, by convention.

25.14 Assembler

Poke provides two ways to execute PVM assembler instructions: an `asm` expression and an `asm` statement.

**asm statements** take the following form:

```
asm (template [: outputs [: inputs]])
```

where `template` is the written form of a PVM assembler program, `outputs` a comma separated list of l-values and `inputs` a comma separated list of expressions.

Before the assembler program in `template` is executed, the `inputs` (if any) are pushed on the stack. After the assembler program is executed, it is expected to have left the same number of elements on the stack than `outputs` specified. These values are then assigned to the outputs, in reverse order.

Example:

```
var result = 0;  
asm ("addi; nip2" : result : 10, 20);  
```

After the execution of the `asm` statement above, the value 30 is stored in the variable `result`.

**asm expressions** take the form:

```
asm type: (template [: inputs])
```

where `type` is a simple type specifier and `template` and `inputs` have the same meaning than in `asm` statements. A single output is always expected to be generated on the stack, of type `type`.
Example:

(poke) asm int: ("addi; nip2" : 10, 20) + 2
32

In both *asm* statements and expressions the compiler generates code that tries to determine whether the execution of the assembler code results in the original stack being underflown or overflown. If this is found to happen an exception E_stack is raised.

**E_stack** is also raised in case an *asm* statement or expression leaves a non-representable PVM value as an output. This is for example the case of PVM_NULL, which can’t be represented in Poke.

Note however that the above mentioned tests are not perfect, and it is generally possible to crash the system using *asm* statements or expressions.

### 25.15 Endianness

Byte endianness is an important aspect of encoding data. As a good binary editor poke provides support for both little and big endian, and will soon acquire the ability to encode exotic endianness like PDP endian. Endianness control is integrated in the Poke language, and is designed to be easily used in type descriptions.

#### 25.15.1 .set endian

GNU poke maintains a global variable that holds the current endianness. This is the endianness that will be used when mapping integers whose types do not specify an explicit endianness.

Like other poke global state, this global variable can be modified using the `.set` dot-command:

```
.set endian little
.set endian big
.set endian host
```

The current endianness can be obtained like this:

(poke) .set endian
little

We can easily see how changing the current endianness indeed impacts the way integers are mapped:

(poke) dump :from 0#B :size 4#B :ruler 0 :ascii 0
00000000: 8845 4c46
(poke) .set endian little
(poke) int @ 0#B
0x464c4588
(poke) .set endian big
(poke) int @ 0#B
0x88454c46

#### 25.15.2 Endian in Fields

It is possible to set the endianness of integral fields in struct type descriptors. See Section 25.6.4 [Field Endianness], page 150.

#### 25.15.3 Endian built-ins

As handy as the `.set endian` dot-command may be, it is also important to be able to change the current endianness programmatically from a Poke program. For that purpose, the PKL compiler provides a couple of built-in functions: *get_endian* and *set_endian*. 
Their definitions, along with the specific supported values, look like:

```plaintext
var ENDIAN_LITTLE = 0;
var ENDIAN_BIG = 1;

fun get_endian = int: { ... }
fun set_endian = (int endian) int: { ... }
```

Accessing the current endianness programmatically is especially useful in situations where the data being poked features a different structure, depending on the endianness.

A good (or bad) example of this is the way registers are encoded in eBPF instructions. eBPF is the in-kernel virtual machine of Linux, and features an ISA with ten general-purpose registers. eBPF instructions generally use two registers, namely the source register and the destination register. Each register is encoded using 4 bits, and the fields encoding registers are consecutive in the instructions.

Typical. However, for reasons we won’t be discussing here the order of the source and destination register fields is switched depending on the endianness.

In big-endian systems the order is:

```
dst:4 src:4
```

Whereas in little-endian systems the order is:

```
src:4 dst:4
```

In Poke, the obvious way of representing data whose structure depends on some condition is using an union. In this case, it could read like this:

```plaintext
type BPF_Insn_Regs =
    union
    {
        struct
        {
            BPF_Reg src;
            BPF_Reg dst;
        } le : get_endian == ENDIAN_LITTLE;
        struct
        {
            BPF_Reg dst;
            BPF_Reg src;
        } be;
    }
```

Note the call to the `get_endian` function (which takes no arguments and thus can be called Algol68-style, without specifying an empty argument list) in the constraint of the union alternative. This way, the register fields will have the right order corresponding to the current endianness.

Nifty. However, there is an ever better way to denote the structure of these fields. This is it:

```plaintext
type BPF_Insn_Regs =
    struct
    {
        var little_p = (get_endian == ENDIAN_LITTLE);
        BPF_Reg src @ !little_p * 4#b;
        BPF_Reg dst @ little_p * 4#b;
    }
```
This version, where the ordering of the fields is implemented using field labels, is not only more compact, but also has the virtue of not requiring additional “intermediate” fields like \texttt{le} and \texttt{be} above. It also shows how convenient can be to declare variables inside structs.

Let’s see it in action:

\begin{verbatim}
(poke) BPF_Insn_Regs @ 1#B
BPF_Insn_Regs {src=#<%r4>,dst=#<%r5>}
(poke) .set endian big
(poke) BPF_Insn_Regs @ 1#B
BPF_Insn_Regs {src=#<%r5>,dst=#<%r4>}
\end{verbatim}

Changing the current endianness in constraint expressions is useful when dealing with binary formats that specify the endianness of the data that follows using some sort of tag. This is the case of ELF, for example. The first few bytes in an ELF header conform what is known as the \texttt{e_ident}. One of these bytes is called \texttt{ei_data} and its value specifies the endianness of the data stored in the ELF file.

This is how we handle this in Poke:

\begin{verbatim}
fun elf_endian = (int endian) byte:
  { 
    if (endian == ENDIAN_LITTLE)
      return ELFDATA2LSB;
    else
      return ELFDAT2MSB;
  }

[...]

type Elf64_Ehdr =
  struct
  { 
    struct
    { 
      byte[4] ei_mag : ei_mag[0] == 0x7fUB
                        && ei_mag[1] == 'E'
                        && ei_mag[2] == 'L'
                        && ei_mag[3] == 'F';
      byte ei_class;
      byte ei_data : (ei_data != ELFDATANONE
                      && set_endian (elf_endian (ei_data)));
      byte ei_version;
      byte ei_osabi;
      byte ei_abiversion;
      byte[6] ei_pad;
      offset<byte,B> ei_nident;
    } e_ident;

    [...]
  }; 
\end{verbatim}

Note how \texttt{set_endian} returns an integer value... it is always 1. This is to facilitate its usage in field constraint expressions.
25.16 Mapping

The purpose of poke is to edit IO spaces, which are the files or devices, or memory areas being edited. This is achieved by mapping values. Mapping is perhaps the most important concept in Poke.

25.16.1 IO Spaces

GNU poke supports the abstract notion of IO space, which is an addressable space of Poke objects: integers, strings, arrays, structs, etc. This underlying storage for the IO spaces (which we call IO devices) can be heterogeneous: from a file your file system to the memory of some process.

25.16.1.1 open

The open builtin allows you to create new IO spaces, by opening an IO device. It has the following prototype:

fun open = (string handler, uint<64> flags = 0) int<32>

where handler is a string identifying the IO device that will serve the IO space. This handler can be:

*name*  An auto growing memory buffer.

pid://[0-9]+  The process ID of some process.

/path/to/file  An either absolute or relative path to a file.

nbd://host:port/export
nbd+unix:///export?socket=/path/to/socket  A connection to an NBD server. See Section 23.6 [nbd command], page 119.

flags is a bitmask that specifies several aspects of the operation, including the mode in which the IO space is opened. Its value is usually built by ORing a set of flags that are provided by the compiler. These are:

IOS_F_READ  The IO space is intended to be read.

IOS_F_WRITE  The IO space is intended to be written.

IOS_F_CREATE  If the IO device doesn’t exist, then create it, usually empty.

Note that the specific behaviour of these flags depend on the nature of the IO space that is opened. For example a memory buffer is always truncated at creation by default.

In order to ease the usage of open, a few pre-made bitmaps are provided to specify opening modes:

IOS_M_RDONLY  This is equivalent to IOS_F_READ.

IOS_M_WRONLY  This is equivalent to IOS_F_WRITE.

IOS_M_RDWR  This is equivalent to IOS_F_READ | IOS_F_WRITE.
The `open` builtin returns a non-negative signed 32-bit integer. This number will identify the just opened IOS until it gets closed. The IO space identifiers are allocated sequentially, and are consistently re-used. This means, for example, that to the sequence `open; open; open; close (1); open;` the following IO spaces get allocated: 0, 1, 2, 1.

If there is a problem opening the specified IO device then `open` will raise an `E_no_ios` exception.

### 25.16.1.2 opensub

The `opensub` standard function allows you to create IO spaces that show a sub-region of some other IO space. The prototype is:

```plaintext
fun opensub = (int<32> ios,
               offset<uint<64>,B> base, offset<uint<64>,B> size,
               string name = "",
               uint<64> flags = 0) int<32>
```

where `ios` is the ID of the base IOS, `base` is the offset in `ios` where the sub-range starts and `size` is the size of the range.

The argument `name` is a descriptive name of the contents of the range, and it is empty by default.

The argument `flags` is an ORed value of `IOS_F_` flags. If no explicit `flags` are specified then the sub space inherits the flags of the underlying base IOS. If explicit `flags` are provided and they contradict the flags of the underlying IOS then `E_ios_flags` is raised.

Trying to access a sub space whose base IOS has been closed results in a `E_io` exception.

### 25.16.1.3 openproc

The `openproc` standard function allows you to create IO spaces to access the memory of some running program, given its process ID. The prototype is:

```plaintext
fun openproc = (uint<64> pid, uint<64> flags = 0) int<32>
```

where `pid` is the process ID whose memory we want to poke and `flags` is a set of open flags.

### 25.16.1.4 close

The `close` builtin allows you to destroy IO spaces, closing the underlying IO device. The prototype is:

```plaintext
fun close = (int<32> ios) void
```

where `ios` is some previously created IO space. All pending data is written to the underlying IO device.

If the IO space specified to `close` doesn’t exist then an `E_no_ios` exception is raised.

If errors occurred while closing the IO space, then `E_ios` exception is raised.

### 25.16.1.5 flush

The builtin `flush` performs a “flushing” operation on a given IO space. The prototype is:

```plaintext
fun flush = (int<32> ios, offset<uint<64>,1> offset) void
```

Where `ios` is the IOS identifier where to perform the flush. The semantics associated with the “flushing” operation depends on the kind of IO space:

- Read-only stream IOS will discard already mapped input up to `offset`. Any further attempt of mapping data at that area will cause an `E_eof` exception (for Early Of File ;).
- Flushing is a no-operation for other kind of IO spaces.
25.16.1.6 get_ios
GNU poke maintains a current IO space, which is the last created IO space (this includes IO spaces opened and selected using a dot-command). The builtin get_ios returns this space. It has the following prototype:

```plaintext
fun get_ios = int<32>
```

If there is no IO space, get_ios will raise the E_no_ios exception.

25.16.1.7 set_ios
The set_ios builtin allows you to set a specific IO space as the new current IO space. It has the following prototype:

```plaintext
fun set_ios = (int<32> ios) int<32>
```

where ios is the IO space that will become the current IO space. If the IO space specified to set_ios doesn’t exist, E_no_ios will be raised.

Note that set_ios always returns 1. This is to ease its usage in struct fields constraint expressions.

25.16.1.8 iosearch
The following builtin allows to search for an IO space by name, or handler. It has the following prototype:

```plaintext
fun iosearch = (string handler) int<32>
```

It returns the identifier of the IO space named handler. If no such IO space is found, then the exception E_no_ios is raised.

25.16.1.9 iolist
At any time there are zero or more open IO spaces. The iolist builtin returns an array of identifiers of these IO spaces. It has the following prototype:

```plaintext
fun iolist = int<32>[]
```

If no IO space is currently open then iolist returns the empty array. The ordering of the IO spaces in the array is arbitrary.

25.16.1.10 openset
Generally when an IO space is opened with open it won’t automatically become the current IO space; it will only happens if there wasn’t an IO space previously open.

The standard function openset is like open that always sets the opened IO space as the new current space. It has the following prototype:

```plaintext
fun openset = (string handler, uint<64> flags = 0) int<32>
```

Where the meaning of handler, flags and the returned value are exactly like in open.

25.16.1.11 iosize
The iosize builtin returns the size of a given IO space, as an offset. It has the following prototype:

```plaintext
fun iosize = (int<32> ios = get_ios) offset<uint<64>,1>
```

If the IO space specified to iosize doesn’t exist, E_no_ios will be raised.

25.16.1.12 iohandler
The iohandler builtin returns the handler string of some given IO space. It has the following prototype:

```plaintext
fun iohandler = (int<32> ios = get_ios) string
```

If the IO space specified to iohandler doesn’t exist, E_no_ios will be raised.
25.16.1.13 ioflags
The `ioflags` builtin returns the flags active in a given IO space, encoded in an unsigned 64-bit integer. It has the following prototype:

```c
fun ioflags = (int<32> ios = get_ios) uint<64>
```

If the IO space specified to `ioflags` doesn't exist, `E_no_ios` will be raised.

25.16.1.14 IO Space Hooks
The user can hook in the IO subsystem by installing functions that will be invoked when certain operations on IO spaces are being performed.

The functions in `ios_open_hook` are invoked once a new IO space has been opened.

The functions in `ios_close_pre_hook` are invoked when an IO space is about to be closed. Note that a close_pre hook can prevent the closing operation to be performed by raising an exception.

The functions in `ios_close_hook` are invoked when an IO space has been closed.

The functions in `ios_set_hook` are invoked when an IO space becomes the current IO space.

All the hooks above get the id of an IO space as arguments:

```c
typedef IOS_Hook_Fn = (int<32>)void
```

The different `io*` built-ins can be then used by the handlers in order to fetch additional properties of the IO space. For example:

```c
fun my_open_handler = (int<32> ios) void:
{
    printf ("*** The IO space '%s' (%i32d) has been opened.\n",
        iohandler (ios), ios);
}
```

25.16.2 The Map Operator
Poke values reside in memory, and their in-memory representation is not visible from Poke programs. For example, 32 is a 32-bit signed integer value, and it happens to not be boxed in the Poke Virtual Machine. Therefore, it occupies exactly 32-bit in the memory of the machine running poke. Other values, like arrays for example, are boxed, and they need to store various meta-data.

Regardless of the internal representation, we say these values live “in memory”. Now, it is also possible to “map” a value to some area in some underlying IO space. This is done with the map operator @, which has two alternate syntax:

```c
typedef @ offset
typedef @ ios : offset
```

The ternary version creates a new value using the data located at the offset `offset` in the specified IO space `ios`, which shall be an expression evaluating to a signed 32-bit integer.

The binary version uses the current IO space.

If there is no IO space, or the specified IO space doesn’t exist, an `E_no_ios` exception is raised:

```c
(poke) int @ 0#B
unhandled no IOS exception
```

The value created in a map can be either mapped or not mapped. Mapping simple types produces not mapped values, whereas mapping non-simple types create mapped values.
The value attributes `mapped` and `offset` can be used to check whether a value is mapped or not, and in that case the offset where it is mapped:

```poky
(poke) var p = Packet @ 0#B
(poke) p'mapped
0x1
(poke) p'offset
0x0UL#b
```

Using the `offset` attribute in a not mapped value results in the `E_no_map` exception being raised:

```poky
(poke) [1,2,3]'mapped
0x0
(poke) [1,2,3]'offset
unhandled no map exception
```

If the type specified in the map is not a simple type, like an array or a struct, the resulting value is said to be mapped in the IO space:

```poky
(poke) type Packet = struct { int i; long l; }
(poke) Packet @ 0#B
Packet {i=0x464c457f,l=0x10102L}
(poke) uint<8>[2] @ 0#B
[0x7fUB,0x45UB]
```

A very important idea on Poke mapping is that it should be possible to manipulate mapped and non-mapped values in a transparent way. For example, consider the quick sort implementation in poke’s standard library. The prototype is:

```poky
fun qsort = (any[] array, Comparator cmp_f,
            long left = 0, long right = array'length - 1) void
```

qsort works with both mapped and not-mapped arrays:

```poky
(poke) var a = [2,3,1]
(poke) var b = int[3] @ 0#B
(poke) b
[1179403647,65794,0]
(poke) qsort (a, IntComparator)
(poke) a
[1,2,3]
(poke) qsort (b, IntComparator)
(poke) b
[0,33620224,1179403647]
```

Similarly, you can write functions that operate on abstract entities and data structures such as ELF relocations and sections, DWARF DIEs, etc, and the same code will work with non mapped and mapped values.

### 25.16.3 Mapping Simple Types

Simple values (i.e. integers, offsets, strings) cannot be mapped. Therefore, if the type specified in the map is a simple type, the resulting value will be a regular non-mapped value. Examples:

```poky
(poke) uint<8> @ 0#B
0x7fUB
(poke) string @ 0#B
"ELF"
```
25.16.4 Mapping Structs

Struct and union types can be referred by name in a mapping (@) operation. For example, given a struct type Foo defined as:

```go
type Foo =
struct
{
    int i;
    long l;
}
```

we could get a mapped struct value of that type like this:

```go
var f = Foo @ 128#B;
```

25.16.5 Mapping Arrays

Arrays can be mapped in IO space in three different ways, depending on the characteristics of the type provided to the mapping operator.

25.16.5.1 Array maps bounded by number of elements

When an array type bounded by number of elements is used in a mapping operation, the resulting mapped array is also bounded by number of elements.

For example, this is how we would map an array of four 32-bit signed integers in the current IO space:

```go
(poke) int[4] @ 0#B
[10, 20, 30, 40]
```

Since you can also provide a dynamic array type to the map operator, the number of elements doesn’t need to be constant. For example, given the variable `nelems` has a value of 2:

```go
(poke) var nelems = 2
(poke) int[nelems + 1] @ 0#B
[100, 222, 333]
```

If for whatever reason the exact requested number of elements can’t be mapped, then E_constraint is raised.

If an end-of-file condition happens while mapping the array, because the number of elements specified in the array type, at the given offset, exceeds the capacity of the underlying IO device, an exception is raised and the mapping is not completed:

```go
(poke) int[99999999999] @ 0#B
unhandled EOF exception
```

Likewise, if a constraint fails while performing the mapping (while mapping an array of structs, for example) an exception is raised and the map is aborted.

25.16.5.2 Array maps bounded by size

While dealing with binary formats, it often happens that the number of entities in a collection is given by the space they occupy, rather than the count itself.

For example, consider ELF sections holding relocations. These sections contain a collection of zero or more relocations. The layout of each relocation is specified by the following type:

```go
type Elf64_Rela =
struct
{
    offset<Elf64_Addr,B> r_offset;
    Elf64_Xword r_info;
}
```
Elf64_Sxword r_addend;
};

The section is described by an entry in the ELF sections header table:

type Elf64_Shdr =
struct
{
Elf_Word sh_name;
Elf_Word sh_type;
Elf64_Xword sh_flags;
Elf64_Addr sh_addr;
Elf64_Off sh_offset;
offset<Elf64_Xword,B> sh_size;
Elf_Word sh_link;
Elf_Word sh_info;
Elf64_Xword sh_addralign;
offset<Elf64_Xword,b> sh_entsize;
};

The relevant elements of Elf64_Shdr are sh_offset and sh_size, which indicate the offset of the beginning of the section’s contents, and its size, respectively. At this point, if we wanted to get an array with all the relocations in the section, we could map an array bounded by number of elements like we saw in the previous section, like this:

(poke) Elf64_Rela[sh_size / 1#Elf64_Rela]
[... relocs ...]

However, this approach adolecles from two problems. First, it doesn’t work with any entity type. For an offset like 1#Elf64_Rela to work, it is required to know the size of the type specified as the unit at compile time. In the particular case of Elf64_Rela, that condition is satisfied, but too often that’s not the case. For example, think about a section containing NULL terminated strings: you can’t know the number of strings contained in the section until you actually read it.

Another problem is when the data in the header is corrupt. Using the mapping bounded by number of elements, we wouldn’t realize it. It would be good if the tool would tell us whether the specified size actually holds an exact number of the requested elements.

A mapping bound by size is what we need. Fortunately, as we saw when discussing array types, Poke allows you to specify an offset instead of an integral value, in the array type specification. The right amount of entities (in this case relocations) to strictly satisfy the provided size will be mapped in the IO space. So, in order to obtain an array containing all the relocations in the section, we simply write:

(poke) Elf64_Rela[ehdr.sh_size] @ ehdr.sh_offset
[... relocs ...]

The strictness mentioned above is important. GNU poke will complain (and abort the mapping) if it is not possible to map an exact number of elements. Thus the following mapping would not be successful:

(poke) int[33#b] @ 0#B
unhandled out of map bounds exception

Like in mappings bounded by number of elements, if a constraint fails while performing the mapping, an exception is raised and the map is aborted.

Likewise, if the exact size specified as the array boundaries can’t be achieved, then E_constraint is raised.
25.16.5.3 Unbounded array maps

We mentioned above that if an end-of-file condition happens while performing a mapping (be it bounded by number of elements or bounded by size) an EOF exception is raised, and the mapping operation is aborted.

Unbounded array mappings are performed by using an unbounded array type in the mapping operation, like in:

```
type[] @ 0#B
```

The above construction will map values of type `type` in the IO space until there is an end-of-file condition, or a constraint fails, whatever happens first. When it is a constraint expression that fails, that last element is not included in the mapped array.

Let’s assume a binary file contains a series of blocks, located one after the other, of a kind described by the following struct type:

```
type Block =
    struct
        ... other data ...
    ];
```

we can map the blocks using an unbounded array map:

```
(poke) Block[] @ 0#B
[ ... blocks ... ]
```

If the blocks extend up to the end of the IO space, that many blocks will be mapped. If there is some other content in the file following the blocks, the constraint in the `magic` field will fail and will delimit the map that way (provided the binary format is well designed.)

25.16.5.4 Mapped bounds in bounded arrays

When an array map is bounded, be it by number of elements or by size, the bounding value can be mapped itself. To illustrate how this works, let’s go back to our ELF file and the section containing relocations. First, we map an `Elf64_Shdr` to get the section header:

```
(poke) var shdr = Elf64_Shdr @ offset
(poke) shdr.sh_offset
120#B
(poke) shdr.sh_size
24#B
```

Now we map an array with the relocations themselves, using a map bounded by size, as we learned in the last section:

```
(poke) var relos = ELF64_Rela[shdr.sh_size] @ shdr.sh_offset
(poke) relos'length
3
```

Now, observe that `shdr.sh_size` is mapped itself! This means that, should the section size be modified (to accommodate an extra relocation, for example) the mapping of `relos` will reflect that automatically:

```
(poke) shdr.sh_size = shdr.sh_size + 1#Elf64_Rela
(poke) relos'length
4
```

This is certainly an useful idiom, that is often used while poking around. However, sometimes this is not what we want. If we don’t want the mapping bounds of `relos` to be tied to `shdr`, we can just use a temporary for the size:

```
(poke) var s = shdr.sh_size
```
(poke) var relocs = Elf64_Rela[s] @ shdr.sh_offset
Since simple values (such as the size above) are not mapped, this trick works as intended.

25.16.6 Mapping Functions
Struct fields can be of any type, and that includes function types or closures. This is especially useful to build interfaces.

For orthogonality, it is possible to map function types. The result of the mapping is not very useful though: mapping a function type results in a function with an empty body. If the function returns a value, a default value (zero for integral types, empty arrays for array types, etc) is returned.

Example:

(poke) type Fun = (int) int
(poke) Fun @ 0#B
#<closure>
(poke) (Fun @ 0#B) 10
0x0

25.16.7 Non-strict Mapping
The map operator @ performs what we call a strict mapping. This means that the data integrity of the mapped data is checked for. Often this is what we want.

However, sometimes we have to work with incorrect or incomplete data. In these cases, we want to inspect that data and complete it using poke.

For this purpose poke provides an alternate map operator @! that behaves exactly like the normal operator, but inhibits the control of data integrity.

The attribute `strict can be used to query whether a given value is strict or non-strict. Non-mapped values are strict by definition.

25.16.8 Auto-Remapping
By default poke always tries to handle mapped values in a transparent way, i.e. in the same way than if the values weren’t mapped. To guarantee that the contents of mapped values are always up to date, it issues remaps every time the value gets referenced.

For example, consider the following Poke program:

var arr = X86_Insn[1024];
There, an array of 1024 x86 instructions arr is mapped. Every time the array value is referenced it is re-mapped from the corresponding IO space. For example:

arr[2].opcode = 0x0b;
In the reference above, the whole array should be re-mapped from IO space, because x86 instructions are variable-length, so it is necessary to re-read all the previous values before accessing the element in position 2.

This re-mapping 100% guarantees that the mapped values are up to date. However, this can get very slow, depending on the data structures we are poking at.

poke offers a way to turn this auto re-mapping off. In Poke code:

vm_set_autoremap (0)
Or using the poke application CLI:

(poke) .set autoremap no
When auto-remap is switched off, mapped values are used as-is. It is then the responsibility of the user to explicitly re-map values using the remap operator. Like:

(poke) remap arr
25.16.9 Unmapping

The unary unmap operator has the form:

```
unmap value
```

It gets any value and produces the same value, making it not mapped in case it is a mapped value.

This is useful when we want to read a data structure from the IO space (say, an array of integers) and then use it for storage without changing the underlying IO space. We would do something like:

```(poke) var a = unmap (int[3] @ 10#B)
(poke) a[2] = 100```

25.17 Exception Handling

Sometimes an error or some other unexpected situation arises. Poke provides an exceptions mechanism to deal with these situations.

25.17.1 Exceptions

Exceptions in Poke are values of type `Exception`, which is a struct defined like this:

```type Exception =
struct
  {int<32> code;
   string msg;
  };
```

where `code` identifies the type of the exception, and `msg` is supposed to be a textual description of the exceptional situation.

You can use codes 255 and higher for your own exceptions. For example:

```raise Exception { code = 255; msg = "double upset event" };
```

User-defined exceptions should be registered using `exception_code` function. For example:

```var E_my_exception = Exception {
  code = exception_code,
  msg = "double upset event",
};
```

where the `E_my_exception.code` is a unique number greater than or equal to 255.

Exception codes in the range 0..254 are reserved for poke. These are used in predefined exceptions which are standard, and have specific meanings:

**E_generic**

Generic error.

**E_out_of_bounds**

Out of bounds exception. This can be raised when accessing containers, like arrays and strings.

**E_eof**

End of file exception. This can be raised when mapping in the IO space.

**E Elem**

Invalid element exception. This is raised when attempting to access union fields that do not exist.

**E_constraint**

Constraint violation exception. This is raised when a constraint exception fails while mapping or constructing a struct.
Chapter 25: The Poke Language

25.17.1 Standard exceptions

E_conv Conversion exception. This can be raised while casting values.
E_map No map exception. This is raised when trying to map a not mapped value.
E_div_by_zero Division by zero exception.
E_no_ios No IOS exception. This is raised when the IO space is accessed but there is no IO space.
E_no_return No return exception. This is raised when the end of a non-void function is reached.
E_io Generic IO exception.
E_io_flags Invalid flags were tried while opening an IO device.
E_assert Assertion failure exception. This is raised by assert statement.
E_overflow This exception is raised when signed overflow is detected in an arithmetic operation.
E_perm This exception is raised when some operation can’t be performed due to incorrect (lack of) permissions or capabilities. An example is writing to a read-only IO space.

The exception codes of the standard exceptions are available in the form of EC_* variables. For example, this how you would raise an IO error with a particular message:

```pascal
raise Exception { code = EC_io,
    msg = "fluzo capacitor overheat impedes IO" }
```

25.17.2 try-catch

The try-catch statement provides a way to catch exceptions and handle them.

The simplest form of the statement is:

```pascal
try stmt catch compound_stmt
```

where stmt is any statement and compound_stmt is a compound statement. First, stmt is executed. If during its execution an exception is raised, then compound_stmt is executed.

The second form of the statement allows you to catch just one type of exception:

```pascal
try stmt catch if exp compound_stmt
```

where exp is an expression that should evaluate to an Exception. The handler compound_stmt will only be executed if that specific exception is caught. Any other exception will be re-raised.

The third form of the statement is the most generic:

```pascal
try stmt catch (Exception formal) compound_stmt
```

where formal is a formal argument that contains the exception when compound_stmt is executed.

25.17.3 try-until

The try-until statement allows you to execute instructions until some exception is caught. The syntax is:

```pascal
try stmt until exp
```

where stmt is the statement that will be executed repeatedly until some exception is raised. If the raised exception has type exp then execution continues normally. exp should be an expression that evaluates to an Exception.

This statement is particularly useful for mapping IO spaces until an eof condition occurs. For example, this is how we would compute with every integer in the current IO space:

```pascal
var o = 0#B;
```
try
{
    compute (int @ o);
    o = o + 1#B;
} until E_eof;

It is possible to leave the loop from within stmt using the break statement.

25.17.4 raise

In previous sections we saw how exceptions are usually the side-product of performing certain operations. For example, a division by zero.

However, it is also useful to explicitly raise exceptions. The raise statement can be used for that purpose. Its syntax is:

    raise exception;

where exception is an integer. This integer can be any number, but most often is one of the E_* codes defined in Poke.

25.17.5 exception-predicate

It is often needed to determine whether the execution of some given code raised some particular exception. A possibility is to use a try-catch statement like in the following example, a pretty-printer in an union type:

    method _print = void:
    {
        try print "#<%u32d>", simple_value;
        catch if E_elem { print "%v\n", complex_value; }
    }

This works as intended, but it is somewhat verbose and not that easy to read for anyone not accustomed to the idiom. It is better to use the exception predicate operator, ?!, that has two forms:

    exp ?! exception
    { [statements...] } ?! exception

In the first form, the expression exp is executed. If the execution raises the exception exception then the result of the predicate is 1 (true), otherwise it is 0 (false). The value of the expression is discarded.

In the second form, the compound statement passed as the first operand is executed. If the exception exception is raised, then the result of the predicate is 0 (false), otherwise it is 1 (true).

Using exception predicates the pretty-printer above can be written in a much more readable way:

    method _print = void:
    {
        if (simple_value ?! E_elem)
            print "%v\n", complex_value;
        else
            print "#<%u32d>", simple_value;
    }

Or, alternatively (and slightly more efficiently):

    method _print = void:
    {
        ({ print "#<%u32d>", simple_value; } ?! E_elem)
            && print "%v\n", complex_value;
    }
25.17.6 assert

The `assert` statement allows you to test if a condition is true, if not, the program will raise an exception with code `EC_assert`.

```plaintext
assert (condition)
assert (condition, message)
```

The optional `message` will be part of the `msg` field of raised `Exception` to explain the situation. If no `message` is explicitly specified, `msg` is set to the source code of the expression evaluated as the assert condition.

```plaintext
assert (1 == 1);
assert (0 == 0, "Zero is equal to zero");
```

`assert` is useful for writing unit tests.

25.18 Terminal

Poke programs have access to a text-oriented terminal, that can be used to communicate with the user. The system provides several primitive functions to manipulate the terminal, which are described in the sections below.

25.18.1 Terminal Colors

At every moment the text terminal is configured to use certain foreground and background colors. Initially, these are the default colors, which depend on the underlying terminal capabilities, and maybe also on some system wide configuration setting.

Terminal colors are encoded in triplets of integers signifying RGB colors, i.e. levels of beams for red, green and blue. These triplets are implemented as values of type `int<32>[3]`.

The special value `[-1, -1, -1]` means the default color, for both foreground and background.

There are two predefined variables for this:

```plaintext
var term_default_color = [-1,-1,-1];
var term_defaultbgcolor = [-1,-1,-1];
```

Getting and setting the foreground and background colors is performed using the `term_get_color`, `term_set_color`, `term_get_fgcolor` and `term_set_fgcolor` functions, with signatures:

```plaintext
fun term_get_color = int<32>[3]
fun term_set_color = (int<32>[3] color) void
fun term_getbgcolor = int<32>[3]
fun term_setbgcolor = (int<32>[3] color) void
```

25.18.2 Terminal Styling

Styling of the output sent to the terminal is supported in the form of styling classes. Each class is characterized by a name, a string.

A class is activated by using the function `term_begin_class`, and deactivated by using the function `term_end_class`. Several classes can be activated simultaneously, but they should be deactivated in reverse order. It is down to the implementation to decide how to honor some given class, i.e. to decide how to characterize it physically (visually, or audibly, or using an electrical discharge on the keyboard, or whatever) The class may very well be ignored all together. Poke programs should never rely on how a specific class is implemented.

The `term_begin_class` and `term_end_class` functions have the following signatures:

```plaintext
fun term_begin_class = (string class) void
fun term_end_class = (string class) void
```

Styling classes can overlap, but trying to deactivate them in the wrong order will cause an error in the form of an `E_inval` exception.
25.18.3 Terminal Hyperlinks

The poke terminal supports terminal hyperlinks. Each hyperlink is characterized by an URL, and an ID. The `term_begin_hyperlink` and `term_end_hyperlink` functions have the following signatures:

```plaintext
fun term_begin_hyperlink = (string url, string id) void
fun term_end_hyperlink = void
```

Hyperlinks can overlap, but trying to end an hyperlink when there is no currently open one will result in an `E_generic` exception raised.

25.19 Printing

Poke programs can print text to the standard output in two ways: simple unformatted output, and formatted output.

25.19.1 print

The `print` statement prints the given string to the standard output. `print` outputs text strings verbatim. It can be invoked using two alternative syntaxes, which are equivalent:

```plaintext
print (str);
print str;
```

`print` is simple, but fast. It is good to use it in simple cases where the information to print out doesn’t require any kind of formatting and styling.

25.19.2 printf

The `printf` statement gets a format string and, optionally, a list of values to print. It can be invoked using two alternative syntaxes, which are equivalent:

```plaintext
printf (fmt [, value...])
printf fmt [, value...]
```

The format string `fmt` is printed verbatim to the standard output, but for format tags which start with `%`. These format tags are interpreted especially. Most of the format tags “consume” one of the specified values. Every value in the list shall be described by a tag, or the compiler will signal an error. Likewise, values without a corresponding describing tag is an error. These tags are:

- **%s** Print the argument as a string.
- **%d** Print the integer in decimal.
- **%x** Print the integer in hexadecimal.
- **%o** Print the integer in octal.
- **%b** Print the integer in binary.
- **%c** Print the integer as an ASCII character. This only works with 8 bit integers.

- **%u** Same as `%i`, but for unsigned integers.
- **%c** A shorter way to write `%u8c`. 
These tags accept integral values, that are cast to an integral value of width \texttt{bits} and then interpreted as an IEEE 754 floating-point number. Currently, valid values for \texttt{bits} are 32 and 64.

When using \texttt{%f} tag, the number will be printed in decimal notation in the style \texttt{[-]ddd.ddd}, where the number of digits after the decimal-point character is equal to the \texttt{precision} specification. The default \texttt{precision} for \texttt{%f32} tag is 7 and for \texttt{%f64} is 15.

The \texttt{%e} tag will print the number in the style \texttt{[-]d.ddde+-dd} where there is one digit (which is non-zero if the floating-point number is non-zero) before the decimal-point character and the number of digits after it is equal the \texttt{precision}. The exponent always contains at least two digits; if the value is zero, the exponent is 00.

And \texttt{%g} tag will print the number in style \texttt{%f} or \texttt{%e}. The \texttt{precision} specifies the number of the significant digits. Style \texttt{%e} is used if the exponent from its conversion is less than -4 or greater than or equal to the \texttt{precision}. Trailing zeros are removed from the fractional part of the result; a decimal point appears only if it is followed by at least one digit.

\begin{verbatim}
(poke) printf ('\%f64d\n', 0x40091eb851eb851fUL);
3.140000000000000
(poke) printf ('pi:\%e32d\n', 0x4048f5c3U)
pi:3.1400001e+00
\end{verbatim}

\texttt{%v}

Print the value printed representation of the argument, which can be of any type including complex types like arrays and structs. This is similar to the \texttt{write} operation available in many Lisp systems.

This tag supports an optional numerical argument (restricted to a single digit) that specifies the maximum depth level when printing structures. Example:

\begin{verbatim}
(poke) printf ('\%1v\n', struct { s = struct { i = 10 }, l = 20L });
struct {s=struct {...},l=0x14L}
\end{verbatim}

By default, the depth level is 0, which means no limit.

This tag also support an optional flag that specifies how the value is printed. The supported tags are \texttt{F} (for \texttt{flat}) and \texttt{T} (for \texttt{tree}). The default is \texttt{flat}. Example:

\begin{verbatim}
(poke) printf ('\%Fv\n', struct { s = struct { i = 10 }, l = 20L });
struct {s=struct {i=0xa},l=0x14L}
\end{verbatim}

This tag is mainly intended to be used in pretty-printers.

The following format tags do not consume arguments. They support emitting styled text using the \texttt{libtextstyle} approach of having styling classes that you can customize in a \texttt{.css} file.

\texttt{%<classname>}

Start the styling class with name \texttt{classname}. The class name cannot be empty.

\texttt{%>}

End the last opened styling class. All styling classes should be ended before finishing the format string.
%%  Print % character.

Note that styling classes can be nested, but all classes should be ended before finishing the format string.

If you use a name class, you can define how to style it in the .css file (poke installs and uses poke-default.css but you can set the POKE_STYLE environment variable to point to another css) like this:

```plaintext
.NAME { text-decoration: blink; color : pink; }
```

Examples:

```plaintext
(poke) printf "This is a NAME: %<NAME:xxx%>"
This is a NAME: xxx
(poke) printf "Name: %<string:%s%> Age: %<integer:%i32d%>, "Jose", 39
Name: Jose Age: 39
```

### 25.20 Comments

There are several ways to document your Poke programs: comments of several types and support for separator characters.

#### 25.20.1 Multi-line comments

Poke supports C-like multi-line comments, which is text enclosed between /* and */ sequences. These comments cannot be nested.

#### 25.20.2 Single line comments

C++-like single line comments are supported. Everything after the // sequence is interpreted as a comment, until the end of the line or the end of the file, whatever comes first.

#### 25.20.3 Vertical separator

Poke ignores form feed characters (ASCII code 12, often visualized as ^L). In GNU software, this character is traditionally used to separate conceptually different entities in source files.

### 25.21 Modules

It is common for pickles to depend on stuff defined in other pickles. In such cases, the load language construction can be used to load pickles from your Poke program. The syntax is:

```plaintext
load module;
```

where module is the name of the pickle to load.

For example, your Poke program may want to access some ELF data structures. In that case, we can just do:

```plaintext
/* Pickle to poke the contents of some ELF section. */

load elf;

/* ... code ... */
```

When asked to open a module, poke assumes it is implemented in a file named module.pk. In the example above, it will try to load elf.pk.

The pickles are searched first in the current working directory. If not found, then prefix/share/poke/module.pk is tried next.

If the environment variable POKEADVATDIR is defined, it replaces prefix/share/poke. This is mainly intended to test a poke program before it gets installed in its final location.
Nothing prevents you to load the same pickle twice. This will work if the pickle doesn’t include definitions, but just executes statements. Otherwise, you will likely get an error due to trying to define stuff twice.

There is an alternate syntax of the `load` construction that is useful when the module is implemented in a file whose name doesn’t conform to a Poke identifier. This happens, for example, when the file name contains hyphens. Example:

```poke
load "my-pickle.pk";
```

Note that if you use this variant of `load`, you must specify the full file name, including whatever extension it uses (usually `.pk`).

### 25.22 System

Poke provides several constructions to interact with the operating system. These are described in the subsections below.

#### 25.22.1 getenv

The `getenv` built-in function has the form:

```poke
fun getenv (string name) string:
```

Given the name of an environment variable, it returns a string with its value. If the variable is not defined in the environment, then the `E_inval` exception is raised.

#### 25.22.2 rand

The `rand` built-in function has the form:

```poke
fun rand = (uint<32> seed = 0) int<32>:
```

It returns a pseudo-random number in the range of the unsigned 32-bit integers. If a seed different to zero is provided, it is used to initialize a new sequence of pseudo-random numbers (which includes the one returned.)

The `gettime` built-in function can be used in order to seed the pseudo-random number generator very easily:

```poke
srand (gettime[1])
```

### 25.23 VM

The Poke language provides a set of pre-defined functions which can be used to access and modify properties of the underlying implementation running the Poke programs.

#### 25.23.1 vm_obase

The pre-defined function `vm_obase` returns the current output base in use in the underlying VM. It has the following prototype:

```poke
fun vm_obase = int<32>:
```

#### 25.23.2 vm_set_obase

The pre-defined function `vm_set_obase` sets the output base in the underlying VM. It has the following prototype:

```poke
fun vm_set_obase = (int<32> obase) void:
```

Where `obase` is the output base to set. The base must be one of 2 (for binary), 8 (for octal), 10 (for decimal) or 16 (for hexadecimal). If the provided base is not contained in that set, `vm_set_obase` raises `E_inval`.
25.23.3 vm_opprint
The pre-defined function vm_opprint returns a boolean indicating whether pretty-printers are used when printing struct values, or not. It has the following prototype:

```haskell
fun vm_opprint = int<32>:
```

25.23.4 vm_set_opprint
The pre-defined function vm_set_opprint sets a flag in the underlying VM, indicating whether pretty-printers are used when printing struct values. It has the following prototype:

```haskell
fun vm_set_opprint = (int<32> pretty_print_p) void:
```

25.23.5 vm_oacutoff
The pre-defined function vm_oacutoff returns an integer indicating the current cutoff limit used when printing array values. It has the following prototype:

```haskell
fun vm_oacutoff = int<32>:
```

25.23.6 vm_set_oacutoff
The pre-defined function vm_set_oacutoff sets the current cutoff limit used when printing array values. It has the following prototype:

```haskell
fun vm_set_oacutoff = (int<32> cutoff) void:
```

where `cutoff` is an integer specifying the maximum number of array elements that get printed.

25.23.7 vm_odepth
The pre-defined function vm_odepth returns an integer indicating the maximum depth level used when printing nested structures. It has the following prototype:

```haskell
fun vm_odepth = int<32>:
```

25.23.8 vm_set_odepth
The pre-defined function vm_set_odepth sets the maximum depth level to be used when printing nested structures. It has the following prototype:

```haskell
fun vm_set_odepth = (int<32> depth_level) void:
```

where `depth_level` specifies the number of depth levels in nested structs to consider when printing nested structures.

25.23.9 vm_oindent
The pre-defined function vm_oindent returns an integer indicating the indentation step. It has the following prototype:

```haskell
fun vm_oindent = int<32>:
```

25.23.10 vm_set_oindent
The pre-defined function vm_set_oindent sets the indentation level used when printing nested structures. It has the following prototype:

```haskell
fun vm_set_oindent = (int<32> step) void:
```

where `step` specifies how much to indent when printing nested structures. This value typically translates into the number of white spaces (or tabs) used in terminals, but this must not be relied on since other printing media may interpret it differently.
25.23.11  
**vm_omaps**
The pre-defined function *vm_omaps* returns a boolean indicating whether offset information is included when printing out values. It has the following prototype:

\[
\text{fun vm_omaps = int<32>:}
\]

25.23.12  
**vm_set_omaps**
The pre-defined function *vm_set_omaps* sets whether offset information is included when printing out values. It has the following prototype:

\[
\text{fun vm_set_omaps = (int<32> omaps_p) void:}
\]

25.23.13  
**vm_omode**
The pre-defined function *vm_omode* returns an integer indicating the currently enabled output mode. It has the following prototype:

\[
\text{fun vm_omode = int<32>:}
\]

There are currently two supported output modes:

\[
\text{var VM_OMODE_PLAIN = 0;}
\]

\[
\text{var VM_OMODE_TREE = 1;}
\]

25.23.14  
**vm_set_omode**
The pre-defined function *vm_set_omode* sets the output mode to use by default when printing values. It has the following prototype:

\[
\text{fun vm_set_omode = (int<32> omode) void:}
\]

Where *omode* is one of the *VM_OMODE_* values documented above.

25.23.15  
**vm_autoremap**
The pre-defined function *vm_autoremap* returns a boolean indicating whether auto-remapping of mapped values is switched on. It has the following prototype:

\[
\text{fun vm_autoremap = int<32>:}
\]

25.23.16  
**vm_set_autoremap**
The pre-defined function *vm_set_autoremap* sets whether auto-remapping of mapped values is switched on. It has the following prototype:

\[
\text{fun vm_set_autoremap = (int<32) void:}
\]

25.24  
**Debugging**

25.24.1  
**__LINE__**  and  **__FILE__**
When printing traces it is often useful to include a description of the location of the trace. The poke compiler provides two builtins for this purpose.

**__LINE__**  Expands to an unsigned 64-bit integer containing the current line of the program being compiled.

**__FILE__**  Expands to a string with the name of the file currently being compiled. If the program is read from the standard input (like in the REPL) then this is "<stdin>".
25.24.2 strace

The `strace` built-in function has the prototype:

```plaintext
fun strace = void;
```

It prints out the current contents of the PVM stack. This is especially useful to debug the code generated by the compiler.

25.24.3 rtrace

The `rtrace` built-in function has the prototype:

```plaintext
fun rtrace = void;
```

It prints out the current call stack in the PVM, a function name in each line.
26 The Standard Library

GNU poke ships with a standard library for Poke programs that is available to Poke programs. The following sections detail the facilities provided by the library.

26.1 Standard Integral Types

The Poke standard library provides the following standard integral types.

- **bit**: 1-bit unsigned integer.
- **nibble**: 4-bit unsigned integer.
- **uint8**: 8-bit unsigned integer.
- **uint16**: 16-bit unsigned integer.
- **uint32**: 32-bit unsigned integer.
- **uint64**: 64-bit unsigned integer.
- **int8**: 8-bit signed integer.
- **int16**: 16-bit signed integer.
- **int32**: 32-bit signed integer.
- **int64**: 64-bit signed integer.

26.2 Standard Offset Types

The Poke standard library provides the following standard offset types.

- **off64**: 64-bit signed offset in bits.
- **uoff64**: 64-bit unsigned offset in bits.

26.3 Standard Units

The following list of units are defined in the standard library.

Base units:

- **b**: bits.
- **N**: nibbles.
- **B**: bytes.

Base 10 units:

- **Kb**: kilo bits (1000 bits.)
- **KB**: Kilo bytes (1000 bytes.)
26.4 Conversion Functions

The Poke standard library provides the following functions to do useful conversions.

26.4.1 catos

It is often useful to convert arrays of characters into strings. The standard function catos provides the following interface:

```ml
fun catos = (char[] chars) string: { ... }
```

It builds a string containing the characters in `chars`, and returns it. Examples:

- (poke) catos ([‘a’,’b’,’c’])
  "abc"
- (poke) catos ([‘\0’])
  ""

Note that if the passed array contains a NULL character '\0' then no further characters are processed. For example:

- (poke) catos ([‘f’,’o’,’o’,’\0’,’b’,’a’,’r’])
  "foo"

26.4.2 stoca

Sometimes we want to store strings in character arrays. The standard function stoca provides the following interface:

```ml
fun stoca = (string s, uint<8>[] ca = uint<8>[](), uint<8> fill = 0) uint<8>[]): { ... }
```

If `ca` has zero length (for example, if the parameter is omitted), the function returns an array with the contents of the string `s`, excluding the terminating NULL. Otherwise, it fills the given array `ca` with the contents of the string `s`. If the string doesn’t fit in the array, then `E_out_of_bounds` is raised. If the length of the string is less than the length of the array, the extra characters are set to the `fill` character, which defaults to \0. The array `ca` is also returned.

26.4.3 strtoi

The standard function strtoi provides the following interface:

```ml
type Strtoi_Result =
  struct
  {
```
fun strtoi = (string str, int base = 10, ulong start = 0) Stroi_Result: { ... }|

It parses a signed integral number in the given base in the string str at position start and returns its value and its length in the val and off fields of a new Stroi_Result instance.

Specifying a start that is greater than or equal to the length of the string causes a E_out_of_bound exception to be raised.

The accepted values for base are 2, 8, 10 (the default) and 16. If any other base is requested an E_inval exception is raised.

Note that this function parses an integer but permits more characters to follow the given integer. As an example, take a look at parsing “12foo” in base 16:

```haskell
#!!# strtoi ("12foo", 16)
Strtoi_Result {
   off=3UL,
   val=303L
}
#!!# strtoi ("12foo", 16, 1)
Strtoi_Result {
   off=3UL,
   val=47L
}
```

26.4.4 atoi

The standard function atoi provides the following interface:

```haskell
fun atoi = (string str, int base = 10) long: { ... }
```

It parses a signed integral number in the given base in the string str and returns it as a signed 64-bit integer.

The accepted values for base are the same as for ‘strtoi’. See Section 26.4.3 [strtoi], page 200, for a list of supported bases.

Note that atoi allows for extra information to be stored in str after the parsed integer. Thus, this works:

```haskell
(poke) atoi ("10foo")
10L
```

26.4.5 ltos

The ltos standard function converts a given long integer into its printed representation in some given base. It has the following prototype:

```haskell
fun ltos = (long i, uint base = 10) string:
```

where i is the number for which to calculate the printed representation, and base is a number between 0 and 16.

26.4.6 stof

The stof standard function converts a given string into a 32-bit floating-point number represented as a uint<32> integer. It has the following prototype:

```haskell
fun stof = (string s) uint<32>:
26.4.7 stod
The `stod` standard function converts a given string into a 64-bit floating-point number represented as a `uint<64>` integer. It has the following prototype:

```
fun stod = (string s) uint<64>:
```

26.5 Array Functions
The Poke standard library provides the following functions to do work on arrays:

26.5.1 reverse
The standard function `reverse` provides the following interface:

```
fun reverse = (any[] a) void:
```

It reverses the elements of the given array.

26.6 String Functions
The Poke standard library provides the following functions to do work on strings:

26.6.1 ltrim
The standard function `ltrim` provides the following interface:

```
fun ltrim = (string s, string cs = " \\	") string: { ... }
```

It returns a copy of the input string `s` with any leading character that also appears in `cs` removed.

26.6.2 rtrim
The standard function `rtrim` provides the following interface:

```
fun rtrim = (string s, string cs = " \\	") string: { ... }
```

It returns a copy of the input string `s` with any trailing character that also appears in `cs` removed.

26.6.3 strchr
The standard function `strchr` provides the following interface:

```
fun strchr = (string s, uint<8> c) int<32>: { ... }
```

It returns the index of the first occurrence of the character `c` in the string `s`. If the character is not found in the string, this function returns the length of the string.

26.6.4 strrchr
The standard function `strrchr` provides the following interface:

```
fun strrchr = (string s, uint<8> c) int<32>: { ... }
```

It returns the index of the last occurrence of the character `c` in the string `s`. If the character is not found in the string, this function returns -1.

26.6.5 strstr
The standard function `strstr` provides the following interface:

```
fun strstr = (string haystack, string needle) int<32>: { ... }
```

It returns the index of the first occurrence of the string `needle` in the string `haystack`. If the needle is not found in the haystack, this function returns the length of the string `haystack`. 
26.6.6 `strtok`

`strtok` is a helper for tokenizing strings. The synopsis of this API are:

```plaintext
type String_Tokenizer =
struct
  {  
    uint<64> i;
    string str;
    computed uint<32> more;

    method get_more = uint<32>: { ... }

    method peek = char: { ... }
    method pop = char: { ... }

    method pop_number = (int<32> base = 10) int<64>: { ... }

    method popdelim = (string delimiters) string: { ... }
    method poprdelim = (string delimiters) string: { ... }

    method raise_exception = (Exception base, string message) void: { ... }
  }

fun strtok = (string a) String_Tokenizer: { ... }
```

`String_Tokenizer` `strtok` (string `a`)  
[Function]

Creates a new tokenizer for the string `a`, initially on the zero position.

The members of the `String_Tokenizer` class are:

- `uint<64>` `i`  
  Offset to the next character to be tokenized, i.e. to the first character that has not already been consumed.

- `string` `str`  
  The string being tokenized. This string is never tokenized.

- `uint<32>` `more`  
  A read-only computed property whose value is truthy if there’s more characters and falsey otherwise.

- `char` `poke` ()  
  Returns the first unread character of the string, but does not advance the `i` offset.
  Raises `E_out_of_bounds` if at the end of the string.

- `char` `peek` ()  
  Returns the first unread character of the string, and advances the tokenizer.
  Raises `E_out_of_bounds` if at the end of the string.

- `int<64>` `pop_number` (int<32> `base = 10`)  
  Returns the number at the start of the string and advances the tokenizer in the given `base`. The bases that are supported are the same as for `strto`i. See Section 26.4.3 [strto`i`], page 200, for a list of supported bases.
  Raises `E_out_of_bounds` if at the end of the string.
string popdelim (string delim)  
Returns the substring up to the first character also present in the string delim. Advances the 
tokenizer to after the delimiter character (i.e. it consumes the delimiter character). 
Raises E_out_of_bounds if at the end of the string.

string poprdelim (string delim)  
Returns the substring up to the last character also present in the string delim. Advances the 
tokenizer to after the delimiter character (i.e. it consumes the delimiter character). 
Raises E_out_of_bounds if at the end of the string.

void raise_exception (Exception base, string message)  
Raises a copy of base augmented so that it contains a description of the tokenizer's current 
position, as well as the programmer-specified message.

26.7 Character Functions

The Poke standard library provides the following functions to deal with characters:

The standard function isdigit provides the following interface:

```plaintext
fun isdigit = (uint<8> c) int<32>
```

it returns 0 when the given ASCII character c is not a decimal digit, otherwise it returns a 
non-zero value.

The standard function isxdigit provides the following interface:

```plaintext
fun isxdigit = (uint<8> c) int<32>
```

it returns 0 when the given ASCII character c is not a hexadecimal digit, otherwise it returns a 
non-zero value.

26.8 Values Functions

The Poke standard library provides the following functions to handle values in general:

26.8.1 eoffset

The standard function eoffset provides the following interface:

```plaintext
fun eoffset = (any val, string name) offset<uint<64>,b>
```

It returns the offset of the element having the given name in the given composite value. If the 
value doesn’t contain an element with the given name then the exception E_inval is raised.

26.9 IO Space Functions

26.9.1 with_cur_ios

The standard function with_cur_ios provides the following interface:

```plaintext
fun with_cur_ios = (int<32> ios, 
  Pk_With_Ios_Fn do = lambda void:{},
  int<32> endian = get_endian) void:
```

Where ios is an IO space identifier, do is a function of type ()void that defaults to a function 
that does nothing, and endian is the endianness to use by default when accessing ios.

When invoked it switches to the given IO space and executes the given function. Once the 
function finishes executing, either by returning or by the raise of an exception, the current IO 
space and endianness are restored to their previous values.
26.9.2 with_temp_ios

The standard function with_temp_ios provides the following interface:

```plaintext
fun with_temp_ios = (string handler = pk_get_unique_mem_ios_handler,
    uint<32> flags = 0,
    Pk_With_Ios_Fn do = lambda void:{},
    int<32> endian = get_endian) void:
```

Where *handler* is the handler to use for the IO space.

*flags* are the flags passed to open when opening the temporary IO space. Defaults to 0, which means to use whatever opening mode makes more sense depending on the kind of the IO space and it's permissions.

*do* is a function of type ()void. Defaults to a function that does nothing.

*endian* is the endianness to use by default when accessing the temporary IO space. Defaults to the current endianness.

When invoked it opens a IO space, like openset, but takes care of calling close and restoring the original current IO space and endianness after the lambda returns or raises an exception.

It can be used to deal with files without risk of leaking file descriptors.

```plaintext
with_cur_ios
:handler "*buf*"
:do lambda void:
{
    var arr = uint<32>[1] 0#B;
    arr[0] = 0x1234;
    printf("%v", byte[4] 0#b);
}
```

26.10 Sorting Functions

26.10.1 qsort

The standard function qsort has the following prototype:

```plaintext
fun qsort = (any[] array, Comparator cmp_f,
    long left = 0,
    long right = array'length - 1) void
```

where *array* is the array to sort, *cmp_f* is a comparator function, *left* is the index of the first array element to include in the sorting, and *right* is the index of the last array element to include in the sorting. Both *left* and *right* are optional, and the default is to cover the whole array.

The comparator function *cmp_f* should have the following prototype:

```plaintext
type Comparator = (any,any)int<32>;
```

for example:

```plaintext
fun CompareInts = (any a, any b) int<32>:
{
    var ai = a as int<32>;
    var bi = b as int<32>;
    if (ai == bi)
        return 0;
    else if (ai > bi)
        return 1;
    else
```
return -1;
}

26.11 CRC Functions

Many file formats use checksums of one sort or another. Therefore you may want to write such a checksum or verify a checksum in a constrained field. See Section 25.6.6 [Field Constraints], page 151.

Some formats use simple additive checksums. Another common checksum is the Cyclic Redundancy Checksum (CRC). The standard function crc32 calculates the 32 bit CRC defined by ISO-3309.

fun crc32 = (byte[] buf) uint<32>: {...}

This function returns the 32 bit CRC for the data contained in the array buf.

26.12 Dates and Times

Often a format encodes a date and time expressed as the number of seconds since midnight, January 1st 1970. You could map these simply as integers. However, the standard library provides two types POSIX_Time32 and POSIX_Time64 which include pretty-printers to display the date in a human readable format. The definition is:

type POSIX_Time
size = struct
{
    uint<size> seconds;

    method _print = void:
    { ... }
}

where size is either 32 or 64. When pretty printing is enabled, a mapped value of these types will display similar to

#<2019-Dec-12 8:54:56>

whereas when pretty printing is not enabled, this example would be displayed as:

POSIX_Time32 {seconds=1576140896U}

Note that timestamps of this type do not account for leap seconds and are agnostic towards timezone.

Occasionally you might wish to print an unmapped timestamp value in a human readable format. To do this, you can use the ptime function, which is defined as follows:

fun ptime = (uint<64> seconds) void:
{ ... }

This pickle also provides a type Timespec that can store Unix times to nanosecond precision, and has the form:

type Timespec = struct
{
    int<64> sec;
    int<64> nsec;
};

The function gettimeofday uses the gettime builtin in order to construct an instance of Timespec. For example:

(poke) gettimeofday
Timespec {
26.13 Offset Functions

26.13.1 alignto

The alignto function has the prototype:

```plaintext
fun alignto = (uoff64 offset, uoff64 to) uoff64:
```

It returns an offset that is the result of aligning the given offset to the given alignment to.

26.14 Other Standard Library Functions

The Poke standard library also provides the following functions that do not fit into the previous few categories:

26.14.1 GNU poke Version String Parsing Utilities

The Poke standard library provides utilities for parsing and comparing GNU poke versions, to allow you to implement conditional code paths or to check prerequisites.

```plaintext
string pk_version
```

Version string of the current instance of GNU poke.

Note that these functions are not generic to any version string, as they assume and verify the version strings generated by the GNU poke build system.

The GNU poke version string that this family of functions accepts fits the following template:

`X.Y[.Z][-BRANCH-NN][-gXDIGITS][-dirty]`. Individually, these components are:

- `X` The major component of this GNU poke version. Mandatory.
- `Y` The minor component of this GNU poke version. Mandatory.
- `Z` The subminor component of this GNU poke version. Optional.
- `BRANCH` A free-form string signifying the current branch a given GNU poke build comes from. Optional. It has two special values:
  - `maint` For maintenance branches.
  - `dev` For the master development branch.

All values other than `dev` are considered equal and lower than `dev` by the comparison helper described below.

- `NN` The number commits on `BRANCH` since the `X.Y[.Z]` tag. Present if and only if `BRANCH` is present. This component is also called the offset.
- `XDIGITS` The abbreviated commit hash this build was generated on. For the purposes of these functions, it is optional, however, in practice, it can only appear when `BRANCH` is also present. Due to the `-g` prefix, this component also makes a poke version string appropriate for Git operations, for example: `git show 3.0-dev-22-g2e092`.
- `-dirty` This suffix is added if the Git tree this GNU poke version was built from is dirty.
The standard library provides the following structured representation of GNU poke versions:

```go
type Pk_Version =
    struct {
        uint<8> major;
        uint<8> minor;
        uint<8> subminor;
        string branch;
        uint<32> offset;
        string commit;

        uint<8> has_branch_p;
        uint<8> has_subminor_p;
        uint<8> has_commit_p;
        uint<8> dirty_p;
    };

string Pk_Version.to_string ()         [Function]
    Method that returns the printed representation of a version.

Pk_Version pk_version_parse (string version) [Function]
    Parses the string version into a new instance of Pk_Version, or raises E_inval if the string is invalid.

The standard library also provides the following helper function:

int<32> pk_vercmp (any a, any b)         [Function]
    Returns a number greater than, equal to, or lower than zero if a compares greater than, equal to or lower than b, respectively, as a GNU poke version.

    The type of a and b must be either string or Pk_Version, otherwise, this function raises an E_conv.

    This function implements partial ordering, as it’s not possible to distinguish some version numbers as greater or lower than each other, as some could be seen as “lateral” to each other. For instance, consider the strings ‘3.0-a-11-gabcde’ and ‘3.0-b-11-gabcde’. They are both 11 commits ahead of the 3.0 release, but they aren’t on the same lineage, and so, they can’t be considered as greater or lower than each other. In cases like these, pk_vercmp will attempt to compare commit numbers as a crude measure.
27 The Poke Virtual Machine

27.1 PVM Instructions

27.1.1 VM instructions

27.1.1.1 Instruction canary

Synopsys:

\texttt{canary}

This instruction installs a canary to mark the bottom of the stack, which is checked by the ‘exit’ instruction. To be most effective this should be executed before the stack is used for the first time.

Stack: \( (--) \)

27.1.1.2 Instruction exit

Synopsys:

\texttt{exit}

Do some cleanup and finish execution of a PVM program. This checks the stack sentinel installed by the ‘canary’ instruction.

Stack: \( (--) \)

27.1.1.3 Instruction pushend

Synopsys:

\texttt{pushend}

Push the current endianness on the stack. This endianness is part of the global state of the PVM.

Stack: \( (-- \text{ INT}) \)

27.1.1.4 Instruction popend

Synopsys:

\texttt{popend}

Pop a signed integer from the stack and make it the current endianness in the PVM. The possible values for endianness are IOS\_ENDIAN\_LSB and IOS\_ENDIAN\_MSB.

Stack: \( (\text{INT} --) \)

27.1.1.5 Instruction pushob

Synopsys:

\texttt{pushob}

Push output base.

This instruction pushes a signed integer value with the output base that is used when printing PVM values. Valid values are 2, 8, 10 and 16.

Stack: \( (-- \text{ INT}) \)
27.1.1.6 Instruction popob

Synopsys:

```
popob
```

Pop and set output base.

This instruction pops a signed integer from the stack and uses it to set the new output base to be used when printing PVM values. Valid values are 2, 8, 10 and 16. If an invalid value is provided then the instruction is a NOP.

Stack: ( INT -- )

27.1.1.7 Instruction pushom

Synopsys:

```
pushom
```

Push output mode.

This instruction pushes a signed integer value with the output mode that is used when printing PVM values. Valid values are 0 for flat mode, and 1 for tree mode.

Stack: ( -- INT )

27.1.1.8 Instruction popom

Synopsys:

```
popom
```

Pop and set output mode.

This instruction pops a signed integer from the stack and uses it to set the new output mode to be used when printing PVM values. Valid values are 0 for flat mode and 1 for tree mode. If an invalid value is provided then this instruction is a no-op.

Stack: ( INT -- )

27.1.1.9 Instruction pushoo

Synopsys:

```
pushoo
```

Push output offsets mode.

This instruction pushes a boolean encoded in a signed integer value indicating whether to show offsets when printing PVM values.

Stack: ( -- INT )

27.1.1.10 Instruction popoo

Synopsys:

```
popoo
```

Pop and set output offsets mode.

This instruction pops a boolean encoded in a signed integer from the stack and uses it to set the new output offset mode to be used when printing PVM values.

Stack: ( INT -- )
27.1.1.11 Instruction pushoi
Synopsys:

    pushoi

    Push output indentation mode.

    This instruction pushes an integer to the stack with the current indentation step configured in
    the VM. The indentation step determines how many white characters to use in each indentation
    level when printing output.

    Stack: ( -- INT )

27.1.1.12 Instruction popoi
Synopsys:

    popoi

    Pop and set output indentation step mode.

    This instruction pops an integer from the stack and uses it to set the current indentation
    step in the VM. The indentation step determines how many white characters to use in each
    indentation level when printing output.

    Stack: ( INT -- )

27.1.1.13 Instruction pushod
Synopsys:

    pushod

    Push output depth.

    This instruction pushes a signed integer indicating the depth to use when printing PVM
    values.

    Stack: ( -- INT )

27.1.1.14 Instruction popod
Synopsys:

    popod

    Pop and set output depth.

    This instruction pops a signed integer indicating the maximum depth included by the VM
    when printing values.

    Stack: ( INT -- )

27.1.1.15 Instruction pushoac
Synopsys:

    pushoac

    Push output array cutoff.

    This instruction pushes a signed integer indicating the number of elements that the VM
    includes in the printed representation of PVM array values.

    Stack: ( -- INT )
27.1.1.16 Instruction popoac
Synopsys:

    popoac
    Pop and set output array cutoff.
    This instruction pops a signed integer indicating the number of elements that the VM
    includes in the printed representation of PVM array values.
    Stack: ( INT -- )

27.1.1.17 Instruction pushopp
Synopsys:

    pushopp
    Push pretty-print usage.
    This instruction pushes a signed integer indicating whether the VM is configured to use
    pretty-printers.
    Stack: ( -- INT )

27.1.1.18 Instruction popopp
Synopsys:

    popopp
    Pop and set usage of pretty-printers.
    This instruction pops a signed integer indicating whether to use pretty-printers when print-
    ing values and sets it in the VM.
    Stack: ( INT -- )

27.1.1.19 Instruction pushoc
Synopsys:

    pushoc
    Push the current output color to the stack, encoded as a RGB triplet.
    Stack: ( -- INT INT INT )

27.1.1.20 Instruction popoc
Synopsys:

    popoc
    Pop the RGB triplet at the top of the stack and use it to set the new terminal output color.
    Stack: ( INT INT INT -- )

27.1.1.21 Instruction pushobc
Synopsys:

    pushobc
    Push the current output background color to the stack, encoded as a RGB triplet.
    Stack: ( -- INT INT INT )
27.1.1.22 Instruction popobc

Synopsys:

\[ \text{popobc} \]

Pop the RGB triplet at the top of the stack and use it to set the new terminal output background color.

Stack: \(( \text{INT INT INT} -- )\)

27.1.1.23 Instruction sync

Synopsys:

\[ \text{sync} \]

Handle pending signals, and raise exceptions accordingly. This instruction should be emitted in strategic places, such as before backwards jumps and at function prolog, to assure signals are eventually attended to.

Stack: \(( -- )\)

Exceptions: \text{PVM_E_SIGNAL}

27.1.1.24 Instruction pusharem

Synopsys:

\[ \text{pusharem} \]

Push autoremap flag.

This instruction pushes a signed integer indicating whether the VM is in ‘autoremap’ mode.

Stack: \(( -- \text{ INT} )\)

27.1.1.25 Instruction poparem

Synopsys:

\[ \text{poparem} \]

Pop and set the autoremap flag.

This instruction pops a signed integer from the stack and sets it as the new value of the ‘autoremap’ flag.

Stack: \(( \text{INT -- } )\)

27.1.2 IOS related instructions

27.1.2.1 Instruction open

Synopsys:

\[ \text{open} \]

Open a new IO space. The handler string and a set of flags are passed on the stack. The descriptor of the opened IOS is pushed to the stack as a signed integer.

If there is no other IO space opened when this instruction is executed, then the just opened space becomes the current IO space.

If there is an error condition opening the IO space, a negative number indicating the condition is pushed on the stack. Note that valid IOS descriptors are non-negative. The possible error conditions are:

-1 for an unspecified error condition. -3 invalid flags specified -4 memory allocation failure. -5 end of file -6 invalid argument passed to open -7 IO space already opened -8 Insufficient permissions to perform the requested operation.

Stack: \(( \text{STR ULONG -- INT} )\)
27.1.2.2 Instruction close

Synopsys:

\texttt{close}

Close an IO space. The descriptor of the space to close is provided on the stack as a signed integer.

If the specified IO space doesn’t exist, this instruction pushes PVM\_E\_NO\_IOS. If the operation fails, it pushes PVM\_E\_IO. Otherwise, it pushes PVM\_NULL.

Stack: ( INT -- EXCEPTION|null )

27.1.2.3 Instruction flush

Synopsys:

\texttt{flush}

Flush an IO space. The descriptor of the space to flush, and the bit-offset up to which perform the flushing are provided on the stack.

If the specified IO space doesn’t exist, this instruction pushes PVM\_E\_NO\_IOS. If the operation fails, it pushes PVM\_E\_IO. Otherwise, it pushes PVM\_NULL.

Stack: ( INT ULONG -- EXCEPTION|null )

27.1.2.4 Instruction pushios

Synopsys:

\texttt{pushios}

Push the descriptor of the current IO space on the stack, as a signed integer. If no IO space is currently opened, push a negative number.

Stack: ( -- INT )

27.1.2.5 Instruction popios

Synopsys:

\texttt{popios}

Pop an IO space descriptor from the stack and set it as the current IO space. If the specified descriptor doesn’t identify an IO space, raise PVM\_E\_NO\_IOS.

Stack: ( INT -- )

Exceptions: PVM\_E\_NO\_IOS

27.1.2.6 Instruction ioflags

Synopsys:

\texttt{ioflags}

Push an unsigned 64-bit integer with the flags of the given IO space on the stack. The IO space is identified by a descriptor, which is a signed integer. If the given IO space doesn’t exist, raise PVM\_E\_NO\_IOS.

Stack: ( INT -- INT ULONG )

Exceptions: PVM\_E\_NO\_IOS
27.1.2.7 Instruction isize

Synopsys:

```
iosize
```

Push the size of the given IO space on the stack, as an offset. The IO space is identified by a
descriptor, which is a signed integer. If the given IO space doesn’t exist, raise PVM_E_NO_IOS.

Stack: ( INT -- INT OFF )

Exceptions: PVM_E_NO_IOS

27.1.2.8 Instruction ionum

Synopsys:

```
ionum
```

Push the number of IO spaces on the stack.

Stack: ( -- ULONG )

27.1.2.9 Instruction ioref

Synopsys:

```
ioref
```

Given an index ULONG, push the descriptor of the IO space on the stack as a signed integer.
If the provided index is out of bounds, then raise PVM_E_OUT_OF_BOUNDS.

Stack: ( ULONG -- ULONG IOS )

Exceptions: PVM_E_OUT_OF_BOUNDS

27.1.2.10 Instruction iohandler

Synopsys:

```
iohandler
```

Push the handler of the given IO space on the stack, as a string. The IO space is identified by a
descriptor, which is a signed integer. If the given IO space doesn’t exist, raise PVM_E_NO_IOS.

Stack: ( INT -- INT OFF )

Exceptions: PVM_E_NO_IOS

27.1.2.11 Instruction iogetb

Synopsys:

```
iogetb
```

Each IO space has a bias associated with it, which by default is 0 bits. This bias is applied
to the offset given to every read/write operation.

This instruction pushes the bias associated to the given IO space to the stack, as an offset.
If the given IO space doesn’t exist then the exception PVM_E_NO_IOS is raised.

Stack: ( INT -- INT OFF )

Exceptions: PVM_E_NO_IOS

27.1.2.12 Instruction iosetb

Synopsys:

```
iosetb
```

Each IO space has a bias associated with it, which by default is 0 bits. This bias is applied
to the offset given to every read/write operation.
This instruction sets the bias associated to the given IO space. The bias is specified as an offset. If the given IO space doesn’t exist, the exception PVM_E_NO_IOS is raised.

Stack: ( OFF INT -- OFF )
Exceptions: PVM_E_NO_IOS

27.1.3 Function management instructions

27.1.3.1 Instruction call

Synopsys:

\texttt{call}

Call a closure on the stack, passing the specified arguments. After the execution of the closure, control is transferred to the instruction immediately following the call instruction.

Stack: ( ARG1 \ldots ARGN CLOSURE -- RETVAL )

27.1.3.2 Instruction prolog

Synopsys:

\texttt{prolog}

Prepare the PVM for the execution of a function. This instruction shall be the target of every ‘call’ instruction and shall be the first instruction in every function body.

Stack: ( -- )

27.1.3.3 Instruction return

Synopsys:

\texttt{return}

Return from a function. A function can have many ‘return’ instructions.

Stack: ( -- )

27.1.4 Environment instructions

27.1.4.1 Instruction pushf

Synopsys:

\texttt{pushf N}

Push a new lexical frame. If the argument N is bigger than zero, it indicates the number of entries in the frame. If N is 0, it means we don’t know how many entries will be stored in the frame.

Stack: ( -- )

27.1.4.2 Instruction popf

Synopsys:

\texttt{popf N}

Pop N lexical frames.

Stack: ( -- )

27.1.4.3 Instruction pushvar

Synopsys:

\texttt{pushvar BACK, OVER}

Retrieve the value of a variable from the lexical environment and push it on the stack. The lexical address of the variable is specified as arguments to the instruction.

Stack: ( -- VAL )
27.1.4.4 Instruction pushtopvar

Synopsys:

```
pushtopvar OVER
```

Retrieve the value of a variable from the top-level frame of the lexical environment and put it on the stack. The OVER part of the lexical address of the variable is specified as an argument to the instruction.

- If the variable is not found then raise E_INVAL.
- Stack: ( -- VAL )

27.1.4.5 Instruction popvar

Synopsys:

```
popvar BACK, OVER
```

Pop a value from the stack and set it as the value of a variable having the lexical address specified in the arguments, in the current lexical environment.

- Stack: ( VAL -- )

27.1.4.6 Instruction regvar

Synopsys:

```
regvar
```

Pop a value from the stack and use it as the value for a new variable in the current lexical environment.

- Stack: ( VAL -- )

27.1.4.7 Instruction duc

Synopsys:

```
duc
```

Make a copy of the closure at the top of the stack, and replace it.

- Stack: ( CLS -- CLS )

27.1.4.8 Instruction pec

Synopsys:

```
pec
```

Put the current lexical environment to the closure at the top of the stack.

- Stack: ( CLS -- CLS )

27.1.5 Printing Instructions

In the following instructions the meaning of the argument BASE is the following:

- 2 - print the number in binary. 8 - print the number in octal. 16 - print the number in hexadecimal. Any other value - print the number in decimal.

27.1.5.1 Instruction printi

Synopsys:

```
printi BITS
```

Given a signed integer and a numeration base in the stack, print the integer to the terminal.

- Stack: ( INT INT -- )
27.1.5.2 Instruction printiu
Synopsys:
   printiu BITS
   Given an unsigned integer and a numeration base in the stack, print the integer to the
   terminal.
   Stack: ( UINT INT -- )

27.1.5.3 Instruction printl
Synopsys:
   printl BITS
   Given a long and a numeration base in the stack, print the integer to the terminal.
   Stack: ( LONG INT -- )

27.1.5.4 Instruction printlu
Synopsys:
   printlu BITS
   Given an unsigned long and a numeration base in the stack, print the integer to the terminal.
   Stack: ( ULONG INT -- )

27.1.5.5 Instruction prints
Synopsys:
   prints
   Print the string at the top of the stack.
   Stack: ( STR -- )

27.1.5.6 Instruction beghl
Synopsys:
   beghl
   Begin an hyperlink, using the URL and ID on the stack.
   Stack: ( STR STR -- )

27.1.5.7 Instruction endhl
Synopsys:
   endhl
   End the current hyperlink.
   If no hyperlink is currently being generated, this instruction pushes int<32>1 in the stack,
   otherwise it pushes int<32>0.
   Stack: ( -- )
   Exceptions: PVM_E_GENERIC

27.1.5.8 Instruction begsc
Synopsys:
   begsc
   Begin the styling class whose name is found on the stack. This class will be in effect in
   subsequent print operations until it is explicitly ended by a 'endsc' instruction.
   Stack: ( STR -- )
27.1.5.9 Instruction endsc

Synopsys:
endsc

End the styling class whose name is found on the stack. This class should have been previously
began by a ‘begsc’ instruction.

If the specified class is not currently being used, this function pushes int<32>0 on the stack.
Otherwise it pushes int<32>1.

Stack: ( STR -- INT )

27.1.6 Format Instructions

In the following instructions the meaning of the argument BASE is the following:

2 - format the number in binary. 8 - format the number in octal. 16 - format the number in
hexadecimal. Any other value - format the number in decimal.

27.1.6.1 Instruction formati

Synopsys:
formati BITS

Given a signed integer and a numeration base in the stack, push the string representation to
the stack.

Stack: ( INT INT -- STR )

27.1.6.2 Instruction formatiu

Synopsys:
formatiu BITS

Given an unsigned integer and a numeration base in the stack, push the string representation
to the stack.

Stack: ( UINT INT -- STR )

27.1.6.3 Instruction formatl

Synopsys:
formatl BITS

Given a long and a numeration base in the stack, push the string representation to the stack.

Stack: ( LONG INT -- STR )

27.1.6.4 Instruction formatlu

Synopsys:
formatlu BITS

Given an unsigned long and a numeration base in the stack, push the string representation
to the stack.

Stack: ( ULONG INT -- STR )

27.1.6.5 Instruction formatf32

Synopsys:
formatf32 STYLE

Given a UINT (that should be interpreted as a 32-bit floating-point number), and a UINT
(as the conversion precision), push the string representation of the floating-point number with
specified precision.
The formatting style is given by a literal parameters. Style 0 corresponds to %f-tag which converts the number in the style \([-\]ddd.ddd where the number of digits after the decimal-point character is the equal to the precision. Style 1 corresponds to %e-tag which converts the number in the style \([-\]d.ddde+\-dd (so called scientific notation). Precision for this style also means the number of digits after the decimal-point character. Style 2 corresponds to %g-tag which choose either %f style or %e based on the length of the representation. For this style, precision specify the number of significant numbers.

Stack: ( UINT UINT -- STR )

27.1.6.6 Instruction formatf64

Synopsys:

    formatf64 STYLE

Given a ULONG (that should be interpreted as a 64-bit floating-point number), and a UINT (as the conversion precision), push the string representation of the floating-point number with specified precision. The formatting style is given by a literal parameters.

The formatting style is given by a literal parameters. Style 0 corresponds to %f-tag which converts the number in the style \([-\]ddd.ddd where the number of digits after the decimal-point character is the equal to the precision. Style 1 corresponds to %e-tag which converts the number in the style \([-\]d.ddde+\-dd (so called scientific notation). Precision for this style also means the number of digits after the decimal-point character. Style 2 corresponds to %g-tag which choose either %f style or %e based on the length of the representation. For this style, precision specify the number of significant numbers.

Stack: ( ULONG UINT -- STR )

27.1.7 Floating-point conversion instructions

27.1.7.1 Instruction stof

Synopsys:

    stof

Given a string containing only a floating-point number, push the corresponding 32-bit floating-point number to the stack, represented as a UINT. On conversion failure, push NULL. Note that leading (not trailing) whitespaces will be ignored.

Stack: ( STR -- UINT )

27.1.7.2 Instruction stod

Synopsys:

    stod

Given a string containing only a floating-point number, push the corresponding 64-bit floating-point number to the stack, represented as a ULONG. On conversion failure, push NULL. Note that leading (not trailing) whitespaces will be ignored.

Stack: ( STR -- ULONG )

27.1.8 Main stack manipulation instructions

27.1.8.1 Instruction push

Synopsys:

    push VAL

Push the value given as an argument to the main stack.

Stack: ( -- VAL )
27.1.8.2 Instruction drop
Synopsys:
  \texttt{drop}
  Pop the value at the top of the main stack, and discard it.
  Stack: ( VAL -- )

27.1.8.3 Instruction drop2
Synopsys:
  \texttt{drop2}
  Pop the two values at the top of the main stack, and discard them.
  Stack: ( VAL VAL -- )

27.1.8.4 Instruction drop3
Synopsys:
  \texttt{drop3}
  Pop the three values at the top of the main stack, and discard them.
  Stack: ( VAL VAL VAL -- )

27.1.8.5 Instruction drop4
Synopsys:
  \texttt{drop4}
  Pop the four values at the top of the stack, and discard them.
  Stack: ( VAL VAL VAL VAL -- )

27.1.8.6 Instruction swap
Synopsys:
  \texttt{swap}
  Exchange the two elements at the top of the stack.
  Stack: ( A B -- B A)

27.1.8.7 Instruction nip
Synopsys:
  \texttt{nip}
  Discard the element at the under top of the main stack.
  Stack: ( A B -- B )

27.1.8.8 Instruction nip2
Synopsys:
  \texttt{nip2}
  Discard the two elements at the under top of the main stack.
  Stack: ( A B C -- C )

27.1.8.9 Instruction nip3
Synopsys:
  \texttt{nip3}
  Discard the three elements at the under top of the main stack.
  Stack: ( A B C D -- D )
27.1.8.10 Instruction dup
Synopsys:

```
dup
```
Push a copy of the element at the top of the main stack.
Stack: ( A -- A A )

27.1.8.11 Instruction over
Synopsys:

```
over
```
Push a copy of the element at the under top of the main stack.
Stack: ( A B -- A B A )

27.1.8.12 Instruction oover
Synopsys:

```
oover
```
Push a copy of the element under the under top of the main stack.
Stack: ( A B C -- A B C A )

27.1.8.13 Instruction rot
Synopsys:

```
rot
```
Rotate the three elements at the top of the main stack, clock-wise.
Stack: ( A B C -- B C A )

27.1.8.14 Instruction nrot
Synopsys:

```
nrot
```
Rotate the three elements at the top of the stack, counter clock-wise.
Stack: ( A B C -- C A B )

27.1.8.15 Instruction tuck
Synopsys:

```
tuck
```
Tuck a copy of the element at the top of the stack down two positions.
Stack: ( A B -- B A B )

27.1.8.16 Instruction quake
Synopsys:

```
quake
```
Swap the two elements at the under top of the stack.
Stack: ( A B C -- B A C )

27.1.8.17 Instruction revn
Synopsys:

```
revn N
```
Reverse the N elements at the top of the stack.
Stack: ( VAL... -- VAL... )
27.1.8.18 Instruction push32

Synopsys:

    push32 HI LO

Push the value passed as two arguments on the stack. This instruction is a workaround to a limitation of Jitter.

Stack: ( -- VAL )

27.1.9 Registers manipulation instructions

27.1.9.1 Instruction pushr

Synopsys:

    pushr REGNO

Push the contents of the register REGNO on the stack.

Stack: ( -- VAL )

27.1.9.2 Instruction popr

Synopsys:

    popr REGNO

Pop the element at the top of the stack and put it in the register REGNO.

Stack: ( VAL -- )

27.1.9.3 Instruction setr

Synopsys:

    setr REGNO

Set the element at the top of the stack to the value of the register REGNO.

Stack: ( -- )

27.1.10 Return stack manipulation instructions

27.1.10.1 Instruction saver

Synopsys:

    saver REGNO

Push the contents of the register REGNO to the return stack.

Stack: ( -- ) ReturnStack: ( - VAL )

27.1.10.2 Instruction restorer

Synopsys:

    restorer REGNO

Pop the element at the top of the return stack and put it in the register REGNO.

Stack: ( -- ) ReturnStack: ( VAL - )

27.1.10.3 Instruction tor

Synopsys:

    tor

Pop an element from the stack and push it in the return stack.

Stack: ( VAL -- ) ReturnStack: ( - VAL )
27.1.10.4 Instruction fromr

Synopsys:

```
fromr
```

Pop an element from the return stack and push it on the stack.

Stack: ( -- VAL) ReturnStack: ( VAL – )

27.1.10.5 Instruction atr

Synopsys:

```
 atr
```

Push a copy of the element at the top of the return stack into the stack.

Stack: ( -- VAL )

27.1.11 Integer overflow checking instructions.
The following instructions check for overflow conditions in signed integer operations.

27.1.11.1 Instruction addiof

Synopsys:

```
addiof
```

Push 1 on the stack if adding the given two signed integer values would overflow. Push 0 on the stack otherwise.

Stack: ( INT INT -- INT INT INT )

27.1.11.2 Instruction addlof

Synopsys:

```
addlof
```

Push 1 on the stack if adding the given two signed long values would overflow. Push 0 on the stack otherwise.

Stack: ( LONG LONG -- LONG LONG INT )

27.1.11.3 Instruction subiof

Synopsys:

```
subiof
```

Push 1 on the stack if subtracting the given two signed integer values would overflow. Push 0 on the stack otherwise.

Stack: ( INT INT -- INT INT INT )

27.1.11.4 Instruction sublof

Synopsys:

```
sublof
```

Push 1 on the stack if subtracting the given two signed long values would overflow. Push 0 on the stack otherwise.

Stack: ( LONG LONG -- LONG LONG INT )
27.1.11.5 Instruction muliof
Synopsys:

muliof

Push 1 on the stack if multiplying the given two signed integer values would overflow. Push 0 on the stack otherwise.
Stack: ( INT INT -- INT INT INT )

27.1.11.6 Instruction mullof
Synopsys:

mullof

Push 1 on the stack if multiplying the given two signed long values would overflow. Push 0 on the stack otherwise.
Stack: ( LONG LONG -- LONG LONG INT )

27.1.11.7 Instruction diviof
Synopsys:

diviof

Push 1 on the stack if dividing the given two signed integer values would overflow. Push 0 on the stack otherwise.
Stack: ( INT INT -- INT INT INT )

27.1.11.8 Instruction divlof
Synopsys:

divlof

Push 1 on the stack if dividing the given two signed long values would overflow. Push 0 on the stack otherwise.
Stack: ( LONG LONG -- LONG LONG INT )

27.1.11.9 Instruction modiof
Synopsys:

modiof

Push 1 on the stack if calculating the remainder of the given two signed integer values would overflow. Push 0 on the stack otherwise.
Stack: ( INT INT -- INT INT INT )

27.1.11.10 Instruction modlof
Synopsys:

modlof

Push 1 on the stack if calculating the remainder of the given two signed long values would overflow. Push 0 on the stack otherwise.
Stack: ( LONG LONG -- LONG LONG INT )

27.1.11.11 Instruction negiof
Synopsys:

negiof

Push 1 on the stack if calculating the negation of the given signed integer value would overflow. Push 0 on the stack otherwise.
Stack: ( INT -- INT INT )
27.1.11.12 **Instruction neglof**

Synopsys:

\[
\text{neglof}
\]

Push 1 on the stack if calculating the negation of the given value would overflow. Push 0 on the stack otherwise.

Stack: \((\text{LONG} \rightarrow \text{LONG INT})\)

27.1.11.13 **Instruction powiof**

Synopsys:

\[
powiof
\]

Push 1 on the stack if calculating the power of the first value by the second would overflow. Push 0 on the stack otherwise.

Stack: \((\text{INT} \rightarrow \text{INT INT})\)

27.1.11.14 **Instruction powlof**

Synopsys:

\[
powlof
\]

Push 1 on the stack if calculating the power of the first value by the second would overflow. Push 0 on the stack otherwise.

Stack: \((\text{LONG LONG} \rightarrow \text{LONG LONG INT})\)

27.1.12 **Arithmetic instructions**

The following instructions assume that both operands have the same size in bits.

27.1.12.1 **Instruction addi**

Synopsys:

\[
\text{addi}
\]

Push the result of adding the two integers at the top of the stack. If the operation would result in overflow, raise PVM_E_OVERFLOW.

Note that this instruction does NOT check for signed overflow, and in case it occurs, the result contents are UB.

Stack: \((\text{INT} \rightarrow \text{INT INT})\)

Exceptions: PVM_E_OVERFLOW

27.1.12.2 **Instruction addiu**

Synopsys:

\[
\text{addiu}
\]

Push the result of adding the two unsigned integers at the top of the stack.

Stack: \((\text{UINT UINT} \rightarrow \text{UINT UINT})\)

27.1.12.3 **Instruction addl**

Synopsys:

\[
\text{addl}
\]

Push the result of adding the two longs at the top of the stack. If the operation would result in overflow, raise PVM_E_OVERFLOW.

Note that this instruction does NOT check for signed overflow, and in case it occurs, the result contents are UB.
Stack: ( LONG LONG -- LONG LONG LONG )
Exceptions: PVM_E_OVERFLOW

27.1.12.4 Instruction addlu
Synopsys:
addlu
Push the result of adding the two unsigned longs at the top of the stack.
Stack: ( ULONG ULONG -- ULONG ULONG ULONG )

27.1.12.5 Instruction subi
Synopsys:
subi
Push the result of subtracting the two integers at the top of the stack.
Note that this instruction does NOT check for signed overflow, and in case it occurs, the result contents are UB.
Stack: ( INT INT -- INT INT INT )

27.1.12.6 Instruction subiu
Synopsys:
subiu
Push the result of subtracting the two unsigned integers at the top of the stack.
Stack: ( UINT UINT -- UINT UINT UINT )

27.1.12.7 Instruction subl
Synopsys:
subl
Push the result of subtracting the two longs at the top of the stack.
Note that this instruction does NOT check for signed overflow, and in case it occurs, the result contents are UB.
Stack: ( LONG LONG -- LONG LONG LONG )

27.1.12.8 Instruction sublu
Synopsys:
sublu
Push the result of subtracting the two unsigned longs at the top of the stack.
Stack: ( ULONG ULONG -- ULONG ULONG ULONG )

27.1.12.9 Instruction muli
Synopsys:
muli
Push the result of multiplying the two integers at the top of the stack.
Note that this instruction does NOT check for signed overflow, and in case it occurs, the result contents are UB.
Stack: ( INT INT -- INT INT INT )
### 27.1.12.10 Instruction muliu

**Synopsys:**

```
muliu
```

Push the result of multiplying the two unsigned integers at the top of the stack.

Stack: ( UINT UINT -- UINT UINT UINT )

### 27.1.12.11 Instruction mull

**Synopsys:**

```
mull
```

Push the result of multiplying the two longs at the top of the stack.

Note that this instruction does NOT check for signed overflow, and in case it occurs, the result contents are UB.

Stack: ( LONG LONG -- LONG LONG LONG )

### 27.1.12.12 Instruction mullu

**Synopsys:**

```
mullu
```

Push the result of multiplying the two unsigned longs at the top of the stack.

Stack: ( ULONG ULONG -- ULONG ULONG ULONG )

### 27.1.12.13 Instruction divi

**Synopsys:**

```
divi
```

Push the result of the integer division of the two integers at the top of the stack. If the denominator is zero, raise PVM_E_DIV_BY_ZERO.

Note that this instruction does NOT check for signed overflow, and in case it occurs, the result contents are UB.

Likewise, this instruction does NOT check for division by zero, so if it is attempted, the poke process will be aborted.

Stack: ( INT INT -- INT INT INT )

Exceptions: PVM_E_DIV_BY_ZERO

### 27.1.12.14 Instruction diviu

**Synopsys:**

```
diviu
```

Push the result of the integer division of the two unsigned integers at the top of the stack. If the denominator is zero, raise PVM_E_DIV_BY_ZERO.

This instruction does NOT check for division by zero, so if it is attempted, the poke process will be aborted.

Stack: ( UINT UINT -- UINT UINT UINT )

Exceptions: PVM_E_DIV_BY_ZERO
27.1.12.15 Instruction divl

Synopsys:

```
divl
```

Push the result of the integer division of the two longs at the top of the stack. If the denominator is zero, raise PVM_E_DIV_BY_ZERO.

Note that this instruction does NOT check for signed overflow, and in case it occurs, the result contents are UB.

Likewise, this instruction does NOT check for division by zero, so if it is attempted, the poke process will be aborted.

Stack: ( LONG LONG -- LONG LONG LONG )

Exceptions: PVM_E_DIV_BY_ZERO

27.1.12.16 Instruction divlu

Synopsys:

```
divlu
```

Push the result of the integer division of the two unsigned longs at the top of the stack. If the denominator is zero, raise PVM_E_DIV_BY_ZERO.

This instruction does NOT check for division by zero, so if it is attempted, the poke process will be aborted.

Stack: ( ULONG ULONG -- ULONG ULONG ULONG )

Exceptions: PVM_E_DIV_BY_ZERO

27.1.12.17 Instruction modi

Synopsys:

```
modi
```

Push the result of the modulus of the two integers at the top of the stack. If the denominator is zero, raise PVM_E_DIV_BY_ZERO.

Note that this instruction does NOT check for signed overflow, and in case it occurs, the result contents are UB.

Likewise, this instruction does NOT check for division by zero, so if it is attempted, the poke process will be aborted.

Stack: ( INT INT -- INT INT INT )

Exceptions: PVM_E_DIV_BY_ZERO

27.1.12.18 Instruction modiu

Synopsys:

```
modiu
```

Push the result of the modulus of the two unsigned integers at the top of the stack. If the denominator is zero, raise PVM_E_DIV_BY_ZERO.

This instruction does NOT check for division by zero, so if it is attempted, the poke process will be aborted.

Stack: ( UINT UINT -- UINT UINT UINT )

Exceptions: PVM_E_DIV_BY_ZERO
27.1.12.19 Instruction modl

Synopsys:

```
modl
```

Push the result of the modulus of the two longs at the top of the stack. If the denominator is zero, raise PVM_E_DIV_BY_ZERO.

Note that this instruction does NOT check for signed overflow, and in case it occurs, the result contents are UB.

This instruction does NOT check for division by zero, so if it is attempted, the poke process will be aborted.

Stack: ( LONG LONG -- LONG LONG LONG )

Exceptions: PVM_E_DIV_BY_ZERO

27.1.12.20 Instruction modlu

Synopsys:

```
modlu
```

Push the result of the modulus of the two unsigned longs at the top of the stack. If the denominator is zero, raise PVM_E_DIV_BY_ZERO.

This instruction does NOT check for division by zero, so if it is attempted, the poke process will be aborted.

Stack: ( ULONG ULONG -- ULONG ULONG ULONG )

Exceptions: PVM_E_DIV_BY_ZERO

27.1.12.21 Instruction negi

Synopsys:

```
egi```

Push the result of the negation of the integer at the top of the stack.

Note that this instruction does NOT check for signed overflow, and in case it occurs, the result contents are UB.

Stack: ( INT -- INT INT )

27.1.12.22 Instruction negiu

Synopsys:

```
negiu
```

Push the result of the negation of the unsigned integer at the top of the stack.

Stack: ( UINT -- UINT UINT UINT )

27.1.12.23 Instruction negl

Synopsys:

```
negl
```

Push the result of the negation of the long at the top of the stack.

Note that this instruction does NOT check for signed overflow, and in case it occurs, the result contents are UB.

Stack: ( LONG -- LONG LONG )
27.1.12.24 Instruction neglu

Synopsys:

neglu

Push the result of the negation of the unsigned long at the top of the stack.

Stack: ( ULONG -- ULONG ULONG )

27.1.12.25 Instruction powi

Synopsys:

powi

Perform the exponentiation of the integer at the under top of the stack. The exponent is the
unsigned integer at the top of the stack. If the exponent is 0, the result is 1.

Note that this instruction does NOT check for signed overflow, and in case it occurs, the
result contents are UB.

Stack: ( INT UINT -- INT UINT INT )

27.1.12.26 Instruction powiu

Synopsys:

powiu

Perform the exponentiation of the unsigned integer at the under top of the stack. The
exponent is the unsigned integer at the top of the stack. If the exponent is 0, the result is 1.

Stack: ( UINT UINT -- UINT UINT UINT )

27.1.12.27 Instruction powl

Synopsys:

powl

Perform the exponentiation of the long at the under top of the stack. The exponent is the
unsigned integer at the top of the stack. If the exponent is 0, the result is 1.

Note that this instruction does NOT check for signed overflow, and in case it occurs, the
result contents are UB.

Stack: ( LONG UINT -- LONG UINT LONG )

27.1.12.28 Instruction powlu

Synopsys:

powlu

Perform the exponentiation of the unsigned long at the under top of the stack. The exponent
is the unsigned integer at the top of the stack. If the exponent is 0, the result is 1.

Stack: ( ULONG UINT -- ULONG UINT ULONG )

27.1.13 Relational instructions

27.1.13.1 Instruction eqi

Synopsys:

eqi

Push 1 on the stack if the two integers at the top of the stack are equal. Otherwise push 0.

Stack: ( INT INT -- INT INT INT )
27.1.13.2 Instruction eqiu
Synopsys:
   eqiu
   Push 1 on the stack if the two unsigned integers at the top of the stack are equal. Otherwise push 0.
   Stack: ( UINT UINT -- UINT UINT UINT )

27.1.13.3 Instruction eql
Synopsys:
   eql
   Push 1 on the stack if the two longs at the top of the stack are equal. Otherwise push 0.
   Stack: ( LONG LONG -- LONG LONG INT )

27.1.13.4 Instruction eqlu
Synopsys:
   eqlu
   Push 1 on the stack if the two unsigned longs at the top of the stack are equal. Otherwise push 0.
   Stack: ( ULONG ULONG -- ULONG ULONG INT )

27.1.13.5 Instruction eqs
Synopsys:
   eqs
   Push 1 on the stack if the two strings at the top of the stack are equal. Otherwise push 0.
   Stack: ( STR STR -- STR STR INT )

27.1.13.6 Instruction nei
Synopsys:
   nei
   Push 1 on the stack if the two integers at the top of the stack are not equal. Otherwise push 0.
   Stack: ( INT INT -- INT INT INT )

27.1.13.7 Instruction neiu
Synopsys:
   neiu
   Push 1 on the stack if the two unsigned integers at the top of the stack are not equal. Otherwise push 0.
   Stack: ( UINT UINT -- UINT UINT INT )

27.1.13.8 Instruction nel
Synopsys:
   nel
   Push 1 on the stack if the two longs at the top of the stack are not equal. Otherwise push 0.
   Stack: ( LONG LONG -- LONG LONG INT )
27.1.13.9 Instruction nelu
Synopsys:

```
nelu
```

Push 1 on the stack if the two unsigned longs at the top of the stack are not equal. Otherwise push 0.

Stack: ( ULONG ULONG -- ULONG ULONG INT )

27.1.13.10 Instruction nes
Synopsys:

```
es
```

Push 1 on the stack if the two strings at the top of the stack are not equal. Otherwise push 0.

Stack: ( STR STR -- STR STR INT )

27.1.13.11 Instruction nn
Synopsys:

```
n
```

Push 0 on the stack if the value at the top of the stack equals PVM_NULL. Otherwise push 1.

Stack: ( VAL -- VAL INT )

27.1.13.12 Instruction nnn
Synopsys:

```
nn
```

Push 1 on the stack if the value at the top of the stack equals PVM_NULL. Otherwise push 0.

Stack: ( VAL -- VAL INT )

27.1.13.13 Instruction lti
Synopsys:

```
lti
```

Push 1 on the stack if the integer at the under top is less that the integer at the top. Otherwise push 0.

Stack: ( INT INT -- INT INT INT )

27.1.13.14 Instruction ltiu
Synopsys:

```
ltiu
```

Push 1 on the stack if the unsigned integer at the under top is less that the unsigned integer at the top. Otherwise push 0.

Stack: ( UINT INT -- UINT UINT INT )

27.1.13.15 Instruction ltl
Synopsys:

```
ltl
```

Push 1 on the stack if the long at the under top is less that the long at the top. Otherwise push 0.

Stack: ( LONG LONG -- LONG LONG INT )
27.1.13.16 Instruction ltlu
Synopsys:

\texttt{ltlu}

Push 1 on the stack if the unsigned long at the under top is less than the unsigned long at the top. Otherwise push 0.

Stack: ( ULONG ULONG -- ULONG ULONG INT )

27.1.13.17 Instruction lei
Synopsys:

\texttt{lei}

Push 1 on the stack if the integer at the under top is less or equal that the integer at the top. Otherwise push 0.

Stack: ( INT INT -- INT INT INT )

27.1.13.18 Instruction leiu
Synopsys:

\texttt{leiu}

Push 1 on the stack if the unsigned integer at the under top is less or equal that the unsigned integer at the top. Otherwise push 0.

Stack: ( UINT UINT -- UINT UINT INT )

27.1.13.19 Instruction lel
Synopsys:

\texttt{lel}

Push 1 on the stack if the long at the under top is less or equal that the long at the top. Otherwise push 0.

Stack: ( LONG LONG -- LONG LONG INT )

27.1.13.20 Instruction lelu
Synopsys:

\texttt{lelu}

Push 1 on the stack if the unsigned long at the under top is less or equal that the unsigned long at the top. Otherwise push 0.

Stack: ( ULONG ULONG -- ULONG ULONG INT )

27.1.13.21 Instruction gti
Synopsys:

\texttt{gti}

Push 1 on the stack if the integer at the under top is greater than the integer at the top. Otherwise push 0.

Stack: ( INT INT -- INT INT INT )

27.1.13.22 Instruction gtiu
Synopsys:

\texttt{gtiu}

Push 1 on the stack if the unsigned integer at the under top is greater than the unsigned integer at the top. Otherwise push 0.

Stack: ( UINT UINT -- UINT UINT INT )
27.1.13.23 Instruction gtl

Synopsys:

gtl

Push 1 on the stack if the long at the under top is greater than the long at the top. Otherwise push 0.

Stack: ( LONG LONG -- LONG LONG INT )

27.1.13.24 Instruction gtlu

Synopsys:

gtlu

Push 1 on the stack if the unsigned long at the under top is greater than the unsigned long at the top. Otherwise push 0.

Stack: ( LONG LONG -- LONG LONG INT )

27.1.13.25 Instruction gei

Synopsys:

gei

Push 1 on the stack if the integer at the under top is greater or equal than the integer at the top. Otherwise push 0.

Stack: ( INT INT -- INT INT INT )

27.1.13.26 Instruction geiu

Synopsys:

geiu

Push 1 on the stack if the unsigned integer at the under top is greater or equal than the unsigned integer at the top. Otherwise push 0.

Stack: ( UINT UINT -- UINT UINT INT )

27.1.13.27 Instruction gel

Synopsys:

gel

Push 1 on the stack if the long at the under top is greater or equal than the long at the top. Otherwise push 0.

Stack: ( LONG LONG -- LONG LONG INT )

27.1.13.28 Instruction gelu

Synopsys:

gelu

Push 1 on the stack if the unsigned long at the under top is greater or equal than the unsigned long at the top. Otherwise push 0.

Stack: ( ULONG ULONG -- ULONG ULONG INT )

27.1.13.29 Instruction lts

Synopsys:

lts

Push 1 on the stack if the string at the under top is less than the string at the top, in lexicographic order. Otherwise push 0.

Stack: ( STR STR -- STR STR INT )
27.1.13.30 Instruction gts

Synopsys:

\texttt{gts}

Push 1 on the stack if the string at the under top is greater than the string at the top, in lexicographic order. Otherwise push 0.

Stack: ( STR STR -- STR STR INT )

27.1.13.31 Instruction ges

Synopsys:

\texttt{ges}

Push 1 on the stack if the string at the under top is greater or equal than the string at the top, in lexicographic order. Otherwise push 0.

Stack: ( STR STR -- STR STR INT )

27.1.13.32 Instruction les

Synopsys:

\texttt{les}

Push 1 on the stack if the string at the under top is less or equal than the string at the top, in lexicographic order. Otherwise push 0.

Stack: ( STR STR -- STR STR INT )

27.1.13.33 Instruction eqc

Synopsys:

\texttt{eqc}

Push 1 on the stack if the two closures at the top of the stack are equal. Otherwise push 0.

Stack: ( CLS CLS -- CLS CLS INT )

27.1.13.34 Instruction nec

Synopsys:

\texttt{nec}

Push 1 on the stack if the two closures at the top of the stack are not equal. Otherwise push 0.

Stack: ( CLS CLS -- CLS CLS INT )

27.1.14 Concatenation instructions

27.1.14.1 Instruction sconc

Synopsys:

\texttt{sconc}

Push the concatenation of the two strings at the top of the stack.

Stack: ( STR STR -- STR STR STR )

27.1.15 Logical instructions
27.1.15.1 Instruction and
Synopsys:
\[
\text{and}
\]
Push the logical and of the two elements at the top of the stack.
Stack: \( \text{INT INT -- INT INT INT} \)

27.1.15.2 Instruction or
Synopsys:
\[
\text{or}
\]
Push the logical or of the two elements at the top of the stack.
Stack: \( \text{INT INT -- INT INT INT} \)

27.1.15.3 Instruction not
Synopsys:
\[
\text{not}
\]
Push the logical not of the element at the top of the stack.
Stack: \( \text{INT -- INT INT} \)

27.1.16 Bitwise instructions

27.1.16.1 Instruction bxori
Synopsys:
\[
\text{bxori}
\]
Push the bitwise exclusive or of the two integers at the top of the stack.
Stack: \( \text{INT INT -- INT INT INT} \)

27.1.16.2 Instruction bxoriu
Synopsys:
\[
\text{bxoriu}
\]
Push the bitwise exclusive or of the two unsigned integers at the top of the stack.
Stack: \( \text{UINT UINT -- UINT UINT UINT} \)

27.1.16.3 Instruction bxorl
Synopsys:
\[
\text{bxorl}
\]
Push the bitwise exclusive or of the two longs at the top of the stack.
Stack: \( \text{LONG LONG -- LONG LONG LONG} \)

27.1.16.4 Instruction bxorlu
Synopsys:
\[
\text{bxorlu}
\]
Push the bitwise exclusive or of the two unsigned longs at the top of the stack.
Stack: \( \text{ULONG ULONG -- ULONG ULONG ULONG} \)
27.1.16.5 Instruction bori

**Synopsys:**

```
bori
```

Push the bitwise or of the two integers at the top of the stack.

**Stack:** ( INT INT -- INT INT INT )

27.1.16.6 Instruction boriu

**Synopsys:**

```
boriu
```

Push the bitwise or of the two unsigned integers at the top of the stack.

**Stack:** ( UINT UINT -- UINT UINT UINT )

27.1.16.7 Instruction borl

**Synopsys:**

```
borl
```

Push the bitwise or of the two longs at the top of the stack.

**Stack:** ( LONG LONG -- LONG LONG LONG )

27.1.16.8 Instruction borlu

**Synopsys:**

```
borlu
```

Push the bitwise or of the two unsigned longs at the top of the stack.

**Stack:** ( ULONG ULONG -- ULONG ULONG ULONG )

27.1.16.9 Instruction bandi

**Synopsys:**

```
bandi
```

Push the bitwise and of the two integers at the top of the stack.

**Stack:** ( INT INT -- INT INT INT )

27.1.16.10 Instruction bandiu

**Synopsys:**

```
bandiu
```

Push the bitwise and of the two unsigned integers at the top of the stack.

**Stack:** ( UINT UINT -- UINT UINT UINT )

27.1.16.11 Instruction bandl

**Synopsys:**

```
bandl
```

Push the bitwise and of the two longs at the top of the stack.

**Stack:** ( LONG LONG -- LONG LONG LONG )

27.1.16.12 Instruction bandlu

**Synopsys:**

```
bandlu
```

Push the bitwise and of the two unsigned longs at the top of the stack.

**Stack:** ( ULONG ULONG -- ULONG ULONG ULONG )
27.1.16.13 Instruction bnoti
Synopsys:

bnoti
Push the bitwise not of the integer at the top of the stack.
Stack: ( INT -- INT INT INT )

27.1.16.14 Instruction bnotiu
Synopsys:

bnotiu
Push the bitwise not of the unsigned integer at the top of the stack.
Stack: ( UINT -- UINT UINT )

27.1.16.15 Instruction bnotl
Synopsys:

bnotl
Push the bitwise not of the long at the top of the stack.
Stack: ( LONG -- LONG LONG )

27.1.16.16 Instruction bnotlu
Synopsys:

bnotlu
Push the bitwise not of the unsigned long at the top of the stack.
Stack: ( ULONG -- ULONG ULONG )

27.1.17 Shift instructions

27.1.17.1 Instruction bsli
Synopsys:

bsli
Left-shift the integer at the under top of the stack the number of bits indicated by the unsigned int at the top of the stack.
If the bit count is equal or bigger than the size of the left operand, then UB happens.
Stack: ( INT UINT -- INT UINT INT )
Exceptions: PVM_E_OUT_OF_BOUNDS

27.1.17.2 Instruction bsliu
Synopsys:

bsliu
Left-shift the unsigned integer at the under top of the stack the number of bits indicated by the unsigned int at the top of the stack.
If the bit count is equal or bigger than the size of the left operand, then UB happens.
Stack: ( UINT UINT -- UINT UINT UINT )
Exceptions: PVM_E_OUT_OF_BOUNDS
27.1.17.3 Instruction bsll

Synopsys:

bsll

Left-shift the long at the under top of the stack the number of bits indicated by the unsigned int at the top of the stack.

If the bit count is equal or bigger than the size of the left operand, then UB happens.

Stack: ( LONG UINT -- LONG UINT LONG )

Exceptions: PVM_E_OUT_OF_BOUNDS

27.1.17.4 Instruction bsllu

Synopsys:

bsllu

Left-shift the unsigned long at the under top of the stack the number of bits indicated by the unsigned int at the top of the stack.

If the bit count is equal or bigger than the size of the left operand, then UB happens.

Stack: ( ULONG UINT -- ULONG UINT ULONG )

Exceptions: PVM_E_OUT_OF_BOUNDS

27.1.17.5 Instruction bsri

Synopsys:

bsri

Right-shift the integer at the under top of the stack the number of tis indicated by the unsigned int at the top of the stack.

Stack: ( INT UINT -- INT UINT INT )

27.1.17.6 Instruction bsriu

Synopsys:

bsriu

Right-shift the unsigned integer at the under top of the stack the number of tis indicated by the unsigned int at the top of the stack.

Stack: ( UINT UINT -- UINT UINT UINT )

27.1.17.7 Instruction bsrl

Synopsys:

bsrl

Right-shift the long at the under top of the stack the number of tis indicated by the unsigned int at the top of the stack.

Stack: ( LONG UINT -- LONG UINT LONG )

27.1.17.8 Instruction bsrlu

Synopsys:

bsrlu

Right-shift the unsigned long at the under top of the stack the number of tis indicated by the unsigned int at the top of the stack.

Stack: ( ULONG UINT -- ULONG UINT ULONG )
27.1.18 Compare-and-swap instructions

27.1.18.1 Instruction swapgti
Synopsys:

\texttt{swapgti}

 Swap the two integers at the top of the stack if the element at the under-top is greater than
the element at the top.

Stack: ( INT INT -- INT INT )

27.1.18.2 Instruction swapgtiu
Synopsys:

\texttt{swapgtiu}

 Swap the two unsigned integers at the top of the stack if the element at the under-top is
greater than the element at the top.

Stack: ( UINT UINT -- UINT UINT )

27.1.18.3 Instruction swapgtl
Synopsys:

\texttt{swapgtl}

 Swap the two longs at the top of the stack if the element at the under-top is greater than
the element at the top.

Stack: ( LONG LONG -- LONG LONG )

27.1.18.4 Instruction swapgtlu
Synopsys:

\texttt{swapgtlu}

 Swap the two unsigned longs at the top of the stack if the element at the under-top is greater
than the element at the top.

Stack: ( ULONG ULONG -- ULONG ULONG )

27.1.19 Branch instructions

27.1.19.1 Instruction ba
Synopsys:

\texttt{ba \texttt{LABEL}}

 Branch unconditionally to the given \texttt{LABEL}.

Stack: ( -- )

27.1.19.2 Instruction bn
Synopsys:

\texttt{bn \texttt{LABEL}}

 Branch to the given \texttt{LABEL} if the value at the top of the stack is PVM_NULL.

Stack: ( VAL -- VAL )
27.1.19.3 Instruction bnn
Synopsys:

```
bnn LABEL
```
Branch to the given LABEL if the value at the top of the stack is not PVM_NULL.
Stack: ( VAL -- VAL )

27.1.19.4 Instruction bzi
Synopsys:

```
bzi LABEL
```
Branch to the given LABEL if the integer at the top of the stack is zero.
Stack: ( INT -- INT )

27.1.19.5 Instruction bziu
Synopsys:

```
bziu LABEL
```
Branch to the given LABEL if the unsigned integer at the top of the stack is zero.
Stack: ( UINT -- UINT )

27.1.19.6 Instruction bzl
Synopsys:

```
bzl LABEL
```
Branch to the given LABEL if the long at the top of the stack is zero.
Stack: ( LONG -- LONG )

27.1.19.7 Instruction bzlu
Synopsys:

```
bzlu LABEL
```
Branch to the given LABEL if the unsigned long at the top of the stack is zero.
Stack: ( ULONG -- ULONG )

27.1.19.8 Instruction bnzi
Synopsys:

```nbzi LABEL
```
Branch to the given LABEL if the integer at the top of the stack is nonzero.
Stack: ( INT -- INT )

27.1.19.9 Instruction bnziu
Synopsys:

```nbziu LABEL
```
Branch to the given LABEL if the unsigned integer at the top of the stack is nonzero.
Stack: ( UINT -- UINT )

27.1.19.10 Instruction bnzl
Synopsys:

```nbzl LABEL
```
Branch to the given LABEL if the long at the top of the stack is nonzero.
Stack: ( LONG -- LONG )
27.1.19.11 Instruction bnzlu
Synopsys:
\[
\text{bnzlu LABEL}
\]
Branch to the given LABEL if the unsigned long at the top of the stack is nonzero.
Stack: ( ULONG -- ULONG )

27.1.20 Conversion instructions

27.1.20.1 Instruction ctos
Synopsys:
\[
\text{ctos}
\]
Convert the character encoded as an unsigned integer at the top of the stack to a string that contains just that character.
Stack: ( UINT -- UINT STR )

27.1.20.2 Instruction itoi
Synopsys:
\[
\text{itoi NBITS}
\]
Convert the integer at the top of the stack to an integer featuring NBITS bits.
NBITS can be any number from 1 to 32.
Stack: ( INT -- INT INT )

27.1.20.3 Instruction itoiu
Synopsys:
\[
\text{itoiu NBITS}
\]
Convert the integer at the top of the stack to an unsigned integer featuring NBITS bits.
NBITS can be any number from 1 to 32.
Stack: ( INT -- INT UINT )

27.1.20.4 Instruction itol
Synopsys:
\[
\text{itol NBITS}
\]
Convert the integer at the top of the stack to a long featuring NBITS bits.
NBITS can be any number from 1 to 64.
Stack: ( INT -- INT LONG )

27.1.20.5 Instruction itolu
Synopsys:
\[
\text{itolu NBITS}
\]
Convert the integer at the top of the stack to an unsigned long featuring NBITS bits.
NBITS can be any number from 1 to 64.
Stack: ( INT -- INT ULONG )
27.1.20.6 Instruction iutoi

Synopsys:
\[
iutoi \text{ NBITS}
\]
Convert the unsigned integer at the top of the stack to an integer featuring NBITS bits.
NBITS can be any number from 1 to 32.
Stack: (UINT -- UINT INT)

27.1.20.7 Instruction iutoiu

Synopsys:
\[
iutoiu \text{ NBITS}
\]
Convert the unsigned integer at the top of the stack to an unsigned integer featuring NBITS bits.
NBITS can be any number from 1 to 32.
Stack: (UINT -- UINT UINT)

27.1.20.8 Instruction iutol

Synopsys:
\[
iutol \text{ NBITS}
\]
Convert the unsigned integer at the top of the stack to a long featuring NBITS bits.
NBITS can be any number from 1 to 64.
Stack: (UINT -- UINT LONG)

27.1.20.9 Instruction iutolu

Synopsys:
\[
iutolu \text{ NBITS}
\]
Convert the unsigned integer at the top of the stack to an unsigned long featuring NBITS bits.
NBITS can be any number from 1 to 64.
Stack: (UINT -- UINT ULONG)

27.1.20.10 Instruction ltoi

Synopsys:
\[
ltoi \text{ NBITS}
\]
Convert the long at the top of the stack to an integer featuring NBITS bits.
NBITS can be any number from 1 to 32.
Stack: (LONG -- LONG INT)

27.1.20.11 Instruction ltoiu

Synopsys:
\[
ltoiu \text{ NBITS}
\]
Convert the long at the top of the stack to an unsigned integer featuring NBITS bits.
NBITS can be any number from 1 to 32.
Stack: (LONG -- LONG UINT)
27.1.20.12 Instruction ltol
Synopsys:

    ltol NBITS
Convert the long at the top of the stack to a long featuring NBITS bits.
NBITS can be any number from 1 to 64.
Stack: ( LONG -- LONG LONG )

27.1.20.13 Instruction ltolu
Synopsys:

    ltolu NBITS
Convert the long at the top of the stack to an unsigned long featuring NBITS bits.
NBITS can be any number from 1 to 64.
Stack: ( LONG -- LONG ULONG )

27.1.20.14 Instruction lutoi
Synopsys:

    lutoi NBITS
Convert the unsigned long at the top of the stack to an integer featuring NBITS bits.
NBITS can be any number from 1 to 32.
Stack: ( ULONG -- ULONG INT )

27.1.20.15 Instruction lutoiu
Synopsys:

    lutoiu NBITS
Convert the unsigned long at the top of the stack to an unsigned integer featuring NBITS bits.
NBITS can be any number from 1 to 32.
Stack: ( ULONG -- ULONG UINT )

27.1.20.16 Instruction lutol
Synopsys:

    lutol NBITS
Convert the unsigned long at the top of the stack to a long featuring NBITS bits.
Stack: ( ULONG -- ULONG LONG )

27.1.20.17 Instruction lutolu
Synopsys:

    lutolu NBITS
Convert the unsigned long at the top of the stack to an unsigned long featuring NBITS bits.
Stack: ( ULONG -- ULONG ULONG )

27.1.21 String instructions
27.1.21.1 Instruction strref
Synopsys:

\textbf{strref}

Given a string and an unsigned long at the top of the stack, push an unsigned integer with the code of the character that occupies that position in the string, on the stack.

The index is zero-based. If it is less than 0 or exceeds the length of the string, then PVM\_E\_OUT\_OF\_BOUNDS is raised.

Stack: ( STR ULONG -- STR ULONG UINT )
Exceptions: PVM\_E\_OUT\_OF\_BOUNDS

27.1.21.2 Instruction strset
Synopsys:

\textbf{strset}

Given a string STR, an index FROM and a string NEWSTR, copy the content of NEWSTR to STR at index FROM.

Index is zero-based.

If FROM >= the size of the string, or if FROM + \text{len(NEWSTR)} > the size of the string, raise the PVM\_E\_OUT\_OF\_BOUNDS exception.

Stack: ( STR ULONG NEWSTR -- STR )
Exceptions: PVM\_E\_OUT\_OF\_BOUNDS

27.1.21.3 Instruction substr
Synopsys:

\textbf{substr}

Given a string and two indices FROM and TO conforming a semi-open interval \([FROM,TO)\), push the substring enclosed by that interval.

Both indexes are zero-based.

If FROM >= the size of the string, or if TO > the size of the string, or if FROM >= TO, raise the PVM\_E\_OUT\_OF\_BOUNDS exception.

Stack: ( STR ULONG(from) ULONG(to) -- STR ULONG(from) ULONG(to) STR )
Exceptions: PVM\_E\_OUT\_OF\_BOUNDS

27.1.21.4 Instruction muls
Synopsys:

\textbf{muls}

Given a string and an unsigned long on the stack, push a new string value whose value is the concatenation of the argument string applied to itself as many times as the unsigned long. If the second argument to muls is 0 then the result of the operation is the empty string.

Stack: ( STR ULONG -- STR ULONG STR )

27.1.21.5 Instruction sprops
Synopsys:

\textbf{sprops}

Given a string STR, set the styling class of the substring with length LEN from index IDX to CLASS.

Stack: ( STR IDX LEN CLASS -- STR )
27.1.21.6 Instruction sproph

Synopsys:

\texttt{sproph}

Given a string STR, set the hyperlink property (which characterized by a URL and an ID) of the substring with length LEN from index IDX.

Stack: \(( STR \, IDX \, LEN \, URL \, ID -- STR )\)

27.1.21.7 Instruction spropc

Synopsys:

\texttt{spropc}

Given a string on the stack, push the copy of the string with all properties cleared.

Stack: \(( STR -- STR )\)

27.1.22 Closure instructions

27.1.22.1 Instruction cgetn

Synopsys:

\texttt{cgetn}

Push the name of the given closure value, or PVM\_NULL if the closure doesn’t have a name.

Stack: \(( CLS \, CLS \, STR|null )\)

27.1.23 Array instructions

27.1.23.1 Instruction mka

Synopsys:

\texttt{mka}

Make a new empty array value.

TYP is the type of the new array.

NELEM is a hint on how many elements to use to initialize the array value. This is to avoid allocating memory that will never be used. Use 0UL when the number of elements in the array are not known in advance; this will make the PVM to choose a reasonable default.

Stack: \(( TYP \, ULONG(\text{nelem}) -- ARR )\)

27.1.23.2 Instruction ains

Synopsys:

\texttt{ains}

Insert a new element VAL, at the end of the array ARR, making it grow.

If IDX is less than the current size of the array, the value is stored in the referred argument.

If IDX is equal or bigger than the current size of the array, the same element is replicated in the previous elements.

Examples:

\(a = [a1, a2, a3]\)

\([a1, a2, a3] \, 2 \, \text{VAL} \, \text{ains} \rightarrow \text{INVAL exception} \, [a1, a2, a3] \, 3 \, \text{VAL} \, \text{ains} \rightarrow [a1, a2, a3, \text{VAL}] \, [a1, a2, a3] \, 5 \, \text{VAL} \, \text{ains} \rightarrow [a1, a2, a3, \text{VAL}, \text{VAL}, \text{VAL}]\)

Stack: \(( \text{ARR} \, \text{IDX} \, \text{VAL} -- \text{ARR} )\)

Exceptions: PVM\_E\_INVAL
27.1.23.3 Instruction arem

Synopsys:

```rem```

Remove an element from an array at the specified index, making it shrink.

If IDX doesn’t correspond to an element in the array, raise PVM.E_OUT_OF_BOUNDS. This always happens if the array is empty.

Stack: `( ARR IDX -- ARR )` Exception: PVM.E_OUT_OF_BOUNDS

27.1.23.4 Instruction aset

Synopsys:

```aset```

Set the value with index ULONG in the array ARR to have the value VAL. The index in ULONG should be in range, since this instruction is not checked.

Stack: `( ARR ULONG VAL -- ARR )`

27.1.23.5 Instruction aref

Synopsys:

```aref```

Given an array ARR and an index ULONG, push the element of the array occupying that position on the stack.

If the provided index is out of bounds, then raise PVM.E_OUT_OF_BOUNDS.

Stack: `( ARR ULONG -- ARR ULONG VAL )`

Exceptions: PVM.E_OUT_OF_BOUNDS

27.1.23.6 Instruction arefo

Synopsys:

```arefo```

Given an array ARR and an index ULONG, push the offset of the element occupying that position in the array.

If the provided index is out of bounds, then raise PVM.E_OUT_OF_BOUNDS.

Stack: `( ARR ULONG -- ARR ULONG OFF )`

Exceptions: PVM.E_OUT_OF_BOUNDS

27.1.24 Struct instructions

27.1.24.1 Instruction mksct

Synopsys:

```mksct```

Given an offset, a list of fields, a list of methods and a struct type, create a struct value and push it on the stack.

Each field is specified as a triplet `[OFF STR VAL]` where OFF is the offset of field, STR the name of the field or PVM.NULL if the field is anonymous, and VAL is a value.

Each method is specified as a tuple `[STR VAL]` where STR is the name of the method and VAL is the closure value corresponding to the method.

Stack: `( OFF [OFF STR VAL]... [STR VAL]... ULONG ULONG TYP -- SCT )`
27.1.24.2 Instruction sset

Synopsys:

\texttt{sset}

Given a struct, a field name and a value, replace the value of the referred struct field with the
given value. If the struct does not have a field with the given name, then raise PVM\_E\_ELEM.

Stack: ( SCT STR VAL -- SCT )

Exceptions: PVM\_E\_ELEM

27.1.24.3 Instruction sseti

Synopsys:

\texttt{sseti}

Given a struct, a field index and a value, replace the value of the referred struct field with
the given value. If the given index does not refer to a struct field, then raise PVM\_E\_ELEM.

Stack: (SCT IDX VAL -- SCT)

Exceptions: PVM\_E\_ELEM

27.1.24.4 Instruction sref

Synopsys:

\texttt{sref}

Given a struct and a field name, push the value contained in the referred struct field on the
stack. If the struct does not have a field with the given name, or if the field is absent from the
struct value then raise PVM\_E\_ELEM.

Stack: (SCT STR -- SCT STR VAL )

Exceptions: PVM\_E\_ELEM

27.1.24.5 Instruction srefo

Synopsys:

\texttt{srefo}

Given a struct and a field name, push the bit-offset of the referred field on the stack. If the
struct does not have a field with the given name, or if the field is absent from the struct value
then raise PVM\_E\_ELEM.

Stack: (SCT STR -- SCT STR BOFF )

Exceptions: PVM\_E\_ELEM

27.1.24.6 Instruction srefmnt

Synopsys:

\texttt{srefmnt}

Given a struct and a method name, push the closure value corresponding to that method on
the stack. If the struct does not have a method with the given name then push PVM\_NULL.

Stack: (SCT STR -- SCT STR CLS )

27.1.24.7 Instruction srefnt

Synopsys:

\texttt{srefnt}

Given a struct and a field name, push the value contained in the struct field on the stack.
If the struct does not have a field with the given name, or if the field is absent from the struct
value then push PVM\_NULL.

Stack: (SCT STR -- SCT STR VAL )
27.1.24.8 Instruction srefi

Synopsys:

\texttt{srefi}

Given a struct and an index, push the value of the field occupying the position specified by the index in the given struct. If the struct doesn’t have that many fields, raise PVM\_E\_OUT\_OF\_BOUNDS.

Stack: ( SCT ULONG -- SCT ULONG VAL )

Exceptions: PVM\_E\_OUT\_OF\_BOUNDS

27.1.24.9 Instruction srefia

Synopsys:

\texttt{srefia}

Given a struct and an index, push 1 if the field occupying the position specified by the index in the given struct is absent. Push 0 otherwise. If the struct doesn’t have that many fields, raise PVM\_E\_OUT\_OF\_BOUNDS.

Stack: ( SCT ULONG -- SCT ULONG INT )

Exceptions: PVM\_E\_OUT\_OF\_BOUNDS

27.1.24.10 Instruction srefio

Synopsys:

\texttt{srefio}

Given a struct and an index, push the offset of the field occupying the position specified by the index in the given struct. If the struct doesn’t have that many fields, raise PVM\_E\_OUT\_OF\_BOUNDS.

Stack: ( SCT ULONG -- SCT ULONG BOFF )

Exceptions: PVM\_E\_OUT\_OF\_BOUNDS

27.1.24.11 Instruction srefin

Synopsys:

\texttt{srefin}

Given a struct and an index, push the name of the field occupying the position specified by the index in the given struct. If the field is anonymous, push PVM\_NULL. If the struct doesn’t have that many fields, raise PVM\_E\_OUT\_OF\_BOUNDS.

Stack: ( SCT ULONG -- SCT ULONG STR )

Exceptions: PVM\_E\_OUT\_OF\_BOUNDS

27.1.24.12 Instruction smodi

Synopsys:

\texttt{smodi}

Given a struct and an index, push the modified flags of the field occupying the position specified by the index in the given struct. If the struct doesn’t have that many fields, raise PVM\_E\_OUT\_OF\_BOUNDS.

Stack: ( SCT ULONG -- SCT ULONG BOOL )

Exceptions: PVM\_E\_OUT\_OF\_BOUNDS

27.1.25 Offset Instructions
27.1.25.1 Instruction mko

Synopsys:

\texttt{mko}

Given an integral magnitude VAL and an offset type, make an offset value of that type and push it on the stack.

Stack: ( VAL TYP -- OFF )

27.1.25.2 Instruction mkoq

Synopsys:

\texttt{mkoq}

Given an integral magnitude VAL and an unit in a ULONG, make an offset type and create an offset value with that type.

Stack: ( VAL ULONG -- OFF )

27.1.25.3 Instruction ogetm

Synopsys:

\texttt{ogetm}

Given an offset OFF, push its magnitude on the stack.

Stack: ( OFF -- OFF VAL )

27.1.25.4 Instruction osetm

Synopsys:

\texttt{osetm}

Given an offset OFF and an integral value VAL, make it the offset’s magnitude.

Stack: ( OFF VAL -- OFF )

27.1.25.5 Instruction ogetu

Synopsys:

\texttt{ogetu}

Given an offset OFF, push its unit on the stack.

Stack: ( OFF -- OFF ULONG )

27.1.25.6 Instruction ogetbt

Synopsys:

\texttt{ogetbt}

Given an offset OFF, push its base type on the stack.

Stack: ( OFF -- OFF TYP )

27.1.26 Instructions to handle mapped values

27.1.26.1 Instruction mm

Synopsys:

\texttt{mm}

Given a value, push 1 on the stack if the value is mapped. Push 0 otherwise.

Stack: ( VAL -- VAL INT )
27.1.26.2 Instruction map
Synopsys:
\[ \texttt{map} \]
Given a value, mark it as as mapped. If the value can’t be mapped then this is a no-operation.
Stack: ( VAL -- VAL )

27.1.26.3 Instruction unmap
Synopsys:
\[ \texttt{unmap} \]
Given a value, mark it as as not mapped. If the value can’t be mapped then this is a no-operation.
Stack: ( VAL -- VAL )

27.1.26.4 Instruction reloc
Synopsys:
\[ \texttt{reloc} \]
Given a value, a IO space expressed in an ulong, and a bit-offset expressed in an ulong, relocate the value to the given bit-offset at the given IO space.
If the given value is not map-able then raise PVM_EINVAL.
Stack: ( VAL ULONG ULONG -- VAL ULONG ULONG )
Exceptions: PVM_EINVAL

27.1.26.5 Instruction ureloc
Synopsys:
\[ \texttt{ureloc} \]
Given a value, undo the last reloc performed on the value.
If the given value is not map-able then raise PVM_EINVAL.
Stack: ( VAL -- VAL )
Exceptions: PVM_EINVAL

27.1.26.6 Instruction mgets
Synopsys:
\[ \texttt{mgets} \]
Given a value, push a boolean indicating whether the value is strict. If the given value is not map-able then push false, i.e. 0.
Stack: ( VAL -- VAL INT )

27.1.26.7 Instruction msets
Synopsys:
\[ \texttt{msets} \]
Given a value and a boolean, set the strictness of the value to the given boolean. If the value is not map-able this is a no-operation.
Stack: ( VAL INT -- VAL )
27.1.26.8 Instruction mgeto
Synopsys:

mgeto

Given a map-able value, push its bit-offset on the stack as an unsigned long. If the given value is not map-able then push PVM_NULL.

Stack: ( VAL -- VAL ULONG )

27.1.26.9 Instruction mseto
Synopsys:

mseto

Given a map-able value an a bit-offset, set its offset to the value. If the given value is not map-able, then the offset is ignored.

Stack: ( VAL ULONG -- VAL )

27.1.26.10 Instruction mgetios
Synopsys:

mgetios

Given a map-able value, push its associated IO space on the stack. If the given value is not map-able, then push PVM_NULL.

Stack: ( VAL -- VAL INT )

27.1.26.11 Instruction msetios
Synopsys:

msetios

Given a map-able value and an IOS descriptor, set it as its associated IO space. If the IOS descriptor is PVM_NULL then it uses the current IO space. If the given value is not map-able then the IO space is ignored.

Stack: ( VAL INT -- VAL )

27.1.26.12 Instruction mgetm
Synopsys:

mgetm

Given a map-able value, push its mapper closure on the stack. If the given value is not map-able, then push PVM_NULL.

Stack: ( VAL -- VAL CLS )

27.1.26.13 Instruction msetm
Synopsys:

msetm

Given a map-able value and a closure, set it as its mapper. If the given value is not map-able then the closure is ignored.

Stack: ( VAL CLS -- VAL )
27.1.26.14 Instruction mgetw

Synopsys:

\texttt{mgetw}

Given a map-able value, push its writer closure on the stack. If the given value is not map-able, then push \texttt{PVM\_NULL}.

Stack: ( VAL -- VAL CLS )

27.1.26.15 Instruction msetw

Synopsys:

\texttt{msetw}

Given a map-able value and a closure, set it as its writer. If the given value is not map-able then the closure is ignored.

Stack: ( VAL CLS -- VAL )

27.1.26.16 Instruction mgetsel

Synopsys:

\texttt{mgetsel}

Given a map-able value in the TOS, push the number of elements to which its mapping is bounded to. If the value is not mapped, or if it is not bounded by number of elements, push \texttt{PVM\_NULL}.

Note that only array values can have mappings bounded by number of elements.

Stack: ( VAL -- VAL ULONG )

27.1.26.17 Instruction msetsel

Synopsys:

\texttt{msetsel}

Given a map-able value and an unsigned long, set it as the mapping bound by number of elements. If the value is not map-able the unsigned long is ignored.

Note that only array values can have mappings bounded by number of elements.

Stack: ( VAL ULONG -- VAL )

27.1.26.18 Instruction mgetsiz

Synopsys:

\texttt{mgetsiz}

Given a map-able value in the TOS, push its mapping size-bound as a bit-offset. If the value is not map-able, or if it is not bounded by size, push \texttt{PVM\_NULL}.

Note that only array values can have mappings bounded by size.

Stack: ( VAL -- VAL ULONG )

27.1.26.19 Instruction msetsiz

Synopsys:

\texttt{msetsiz}

Given a map-able value and a bit-offset, set it as the mapping size-bound. If the value is not map-able, the bit-offset is ignored.

Note that only array values can have mappings bounded by size.

Stack: ( VAL ULONG -- VAL )
27.1.27 Type related instructions

27.1.27.1 Instruction isa

Synopsys:

    isa
    Given a value and a type, push 1 on the stack if the value is of the given type. Push 0 otherwise.
    Stack: ( VAL TYPE -- TYPE VAL INT )

27.1.27.2 Instruction typof

Synopsys:

    typof
    Given a value that is not itself a type, push its type on the stack. Given a value that is a type, push the value on the stack.
    Stack: ( VAL -- VAL TYPE )

27.1.27.3 Instruction isty

Synopsys:

    isty
    Given a value, push 1 on the stack if it is a PVM type. Push 0 otherwise.
    Stack: ( TYPE -- TYPE INT )

27.1.27.4 Instruction tyisi

Synopsys:

    tyisi
    Given a type, push 1 on the stack if it is an int. Push 0 otherwise.
    Stack: ( TYPE -- TYPE INT )

27.1.27.5 Instruction tyisiu

Synopsys:

    tyisiu
    Given a type, push 1 on the stack if it is an uint. Push 0 otherwise.
    Stack: ( TYPE -- TYPE INT )

27.1.27.6 Instruction tyisl

Synopsys:

    tyisl
    Given a type, push 1 on the stack if it is a long. Push 0 otherwise.
    Stack: ( TYPE -- TYPE INT )

27.1.27.7 Instruction tyislu

Synopsys:

    tyislu
    Given a type, push 1 on the stack if it is an ulong. Push 0 otherwise.
    Stack: ( TYPE -- TYPE INT )
27.1.27.8 Instruction tyiso
Synopsys:

\[ \text{tyiso} \]

Given a type, push 1 on the stack if it is an offset. Push 0 otherwise.
Stack: ( TYPE -- TYPE INT )

27.1.27.9 Instruction tyiss
Synopsys:

\[ \text{tyiss} \]

Given a type, push 1 on the stack if it is a string. Push 0 otherwise.
Stack: ( TYPE -- TYPE INT )

27.1.27.10 Instruction tyisa
Synopsys:

\[ \text{tyisa} \]

Given a type, push 1 on the stack if it is an array. Push 0 otherwise.
Stack: ( TYPE -- TYPE INT )

27.1.27.11 Instruction tyisc
Synopsys:

\[ \text{tyisc} \]

Given a type, push 1 on the stack if it is a closure. Push 0 otherwise.
Stack: ( TYPE -- TYPE INT )

27.1.27.12 Instruction tyissct
Synopsys:

\[ \text{tyissct} \]

Given a type, push 1 on the stack if it is a struct. Push 0 otherwise.
Stack: ( TYPE -- TYPE INT )

27.1.27.13 Instruction tyisv
Synopsys:

\[ \text{tyisv} () \]

Given a type, push 1 on the stack if it is a void. Push 0 otherwise.
Stack: ( TYPE -- TYPE INT )

27.1.27.14 Instruction mktyv
Synopsys:

\[ \text{mktyv} \]

Build a "void" type and push it on the stack.
Stack: ( -- TYPE )
27.1.27.15 Instruction mktyi

Synopsys:

\texttt{mktyi}

Given an unsigned long denoting a bit width, and an unsigned int denoting signedness (0 is unsigned, 1 is signed), build a an integral type with these features and push it on the stack.

Stack: \(\text{ULONG UINT -- TYPE}\)

27.1.27.16 Instruction tyigetsz

Synopsys:

\texttt{tyigetsz}

Given an integral type, push its size (in bits) to the stack.

Stack: \(\text{ITYPE -- ITYPE ULONG}\)

27.1.27.17 Instruction tyigetsg

Synopsys:

\texttt{tyigetsg}

Given an integral type, push its sign to the stack. 0 means unsigned and 1 means signed.

Stack: \(\text{ITYPE -- ITYPE INT}\)

27.1.27.18 Instruction mktys

Synopsys:

\texttt{mktys}

Push a string type on the stack.

Stack: \(\ --\ TYPE\)

27.1.27.19 Instruction mktyo

Synopsys:

\texttt{mktyo}

Given a base integral type and an ulong denoting an offset unit (multiple of the base unit) construct an offset type having these features, and push it on the stack.

Stack: \(\text{TYPE ULONG -- TYPE}\)

27.1.27.20 Instruction tyogetm

Synopsys:

\texttt{tyogetm}

Given an offset type, push type of magnitude to the stack.

Stack: \(\text{OTYPE -- OTYPE ITYPE}\)

27.1.27.21 Instruction tyogetu

Synopsys:

\texttt{tyogetu}

Given an offset type, push unit value to the stack.

Stack: \(\text{OTYPE -- OTYPE ULONG}\)
27.1.27.22 Instruction tyogetrt

Synopsys:

\texttt{tyogetrt}

Given an offset type, push the referred type to the stack. This can be PVM\_NULL if the offset type isn’t a reference.

Stack: ( OTYPE -- OTYPE TYPE )

27.1.27.23 Instruction tyosetrt

Synopsys:

\texttt{tyosetrt}

Given an offset type and a referred type, make the offset type a referring type. The referred type can be PVM\_NULL. In this case the resulting offset type is not a referring offset type.

Stack: ( OTYPE TYPE -- OTYPE )

27.1.27.24 Instruction mktya

Synopsys:

\texttt{mktya}

Given an elements type and a bounder closure, build an array type having these features and push it on the stack. The bounder closure can return either PVM\_NULL, or an integer, or an offset as the boundary of the array type.

Stack: ( TYPE BOUNDER -- TYPE )

27.1.27.25 Instruction tyagett

Synopsys:

\texttt{tyagett}

Given an array type, push the type of its elements on the stack.

Stack: ( TYPE -- TYPE TYPE )

27.1.27.26 Instruction tyagetb

Synopsys:

\texttt{tyagetb}

Given an array type, push its bound on the stack.

Stack: ( TYPE -- TYPE (ULONG\mid NULL) )

27.1.27.27 Instruction tyasetb

Synopsys:

\texttt{tyasetb}

Given an array ARR and a closure BOUND, set the later as the array’s bounder function. This is a function that, once executed with no arguments, returns the size of the array or null.

Stack: ( TYPE BOUND -- TYPE )

27.1.27.28 Instruction mktyc

Synopsys:

\texttt{mktyc}

Given a list of argument types, a return type and a number of arguments, build a closure type and push it on the stack.

Stack: ( TYPE\ldots TYPE ULONG -- TYPE )
27.1.27.29 Instruction mktysct

Synopsys:

\[ \text{mktysct} \]

Given a list of field descriptors, a number of fields and a struct type name, build a struct type and push it on the stack.

Each field descriptor has the form \[ \text{[STRING TYPE]} \] and contains the name of the field and its type.

Stack: \[ ( \text{[STRING TYPE]} \ldots \text{ULONG STR} -- \text{TYPE} ) \]

27.1.27.30 Instruction tysctgetc

Synopsys:

\[ \text{tysctgetc} \]

Given a struct type, push its constructor closure to the stack. If no constructor closure is installed in the type, push PVM_NULL.

Stack: \[ ( \text{TYP} -- \text{TYP CLS|null} ) \]

27.1.27.31 Instruction tysctsetc

Synopsys:

\[ \text{tysctsetc} \]

Given a struct type and a closure, install it as the type's constructor.

Stack: \[ ( \text{TYP CLS} -- \text{TYP} ) \]

27.1.27.32 Instruction tysctgetn

Synopsys:

\[ \text{tysctgetn} \]

Given a struct type, push its name to the stack. If the struct type is not named push PVM_NULL.

Stack: \[ ( \text{TYP} -- \text{SCT STR} ) \]

27.1.27.33 Instruction tysctgetnf

Synopsys:

\[ \text{tysctgetnf} \]

Given a struct type, push its number of fields to the stack.

Stack: \[ ( \text{SCT} -- \text{SCT ULONG} ) \]

27.1.27.34 Instruction tysctgetfn

Synopsys:

\[ \text{tysctgetfn} \]

Given a struct type and an index, push the field name to the stack. If the field is not named push PVM_NULL.

Stack: \[ ( \text{SCT ULONG} -- \text{SCT ULONG STR} ) \]

27.1.27.35 Instruction tysctgetft

Synopsys:

\[ \text{tysctgetft} \]

Given a struct type and an index, push the field type to the stack.

Stack: \[ ( \text{SCT ULONG} -- \text{SCT ULONG TYP} ) \]
27.1.28 IO instructions

27.1.28.1 Instruction write

Synopsys:
```
write
```
If the value at the TOS is mapped, then write it to its associated IO space. Otherwise, this
is a no-op.

Stack: ( VAL -- VAL )

Exceptions: PVM_E_IOS_FULL, PVM_E_CONSTRAINT_ERROR

27.1.28.2 Instruction peeki

Synopsys:
```
peeki NENC,ENDIAN,BITS
```
Given an IOS descriptor and a bit-offset, peek an integer value of width BITS bits. The
negative encoding and endianness to be used are specified in the instruction arguments.

If there is a problem performing the operation, this function pushes an exception in the stack.
Otherwise, it pushes the peeked value and PVM_NULL.

Stack: ( INT ULONG -- [INT] EXCEPTION|null )

27.1.28.3 Instruction peekiu

Synopsys:
```
peekiu ENDIAN,BITS
```
Given an IOS descriptor and a bit-offset, peek an unsigned integer value of width BITS bits.
The endianness to be used is specified in the instruction arguments.

If there is a problem performing the operation, this function pushes an exception in the stack.
Otherwise, it pushes the peeked value and PVM_NULL.

Stack: ( INT ULONG -- [INT] EXCEPTION|null )

27.1.28.4 Instruction peekl

Synopsys:
```
peekl NENC,ENDIAN,BITS
```
Given an IOS descriptor and a bit-offset, peek a long value of width BITS bits. The negative
encoding and endianness to be used are specified in the instruction arguments.

If there is a problem performing the operation, this function pushes an exception in the stack.
Otherwise, it pushes the peeked value and PVM_NULL.

Stack: ( INT ULONG -- [LONG] EXCEPTION|null )

27.1.28.5 Instruction peeklu

Synopsys:
```
peeklu ENDIAN,BITS
```
Given an IOS descriptor and a bit-offset, peek an unsigned long value of width BITS bits.
The endianness to be used is specified in the instruction arguments.

If there is a problem performing the operation, this function pushes an exception in the stack.
Otherwise, it pushes the peeked value and PVM_NULL.

Stack: ( INT ULONG -- [ULONG] EXCEPTION|null )
27.1.28.6 Instruction peekdi

Synopsys:

\texttt{peekdi} \texttt{BITS}

Given an IOS descriptor and a bit-offset, peek an integer value of width \texttt{BITS} bits. Use the default endianness and negative encoding.

If there is a problem performing the operation, this function pushes an exception in the stack. Otherwise, it pushes the peeked value and PVM\_NULL.

Stack: ( INT ULONG -- [INT] EXCEPTION\|null )

27.1.28.7 Instruction peekdiu

Synopsys:

\texttt{peekdiu} \texttt{BITS}

Given an IOS descriptor and a bit-offset, peek an unsigned integer value of width \texttt{BITS} bits. Use the default endianness.

If there is a problem performing the operation, this function pushes an exception in the stack. Otherwise, it pushes the peeked value and PVM\_NULL.

Stack: ( INT ULONG -- [UINT] EXCEPTION\|null )

27.1.28.8 Instruction peekdl

Synopsys:

\texttt{peekdl} \texttt{BITS}

Given an IOS descriptor and a bit-offset, peek a long value of width \texttt{BITS} bits. Use the default endianness and negative encoding.

If there is a problem performing the operation, this function pushes an exception in the stack. Otherwise, it pushes the peeked value and PVM\_NULL.

Stack: ( INT ULONG -- [LONG] EXCEPTION\|null )

27.1.28.9 Instruction peekdlu

Synopsys:

\texttt{peekdlu} \texttt{BITS}

Given an IOS descriptor and a bit-offset, peek an unsigned long value of width \texttt{BITS} bits. Use the default endianness.

If there is a problem performing the operation, this function pushes an exception in the stack. Otherwise, it pushes the peeked value and PVM\_NULL.

Stack: ( INT ULONG -- [ULONG] EXCEPTION\|null )

27.1.28.10 Instruction pokei

Synopsys:

\texttt{pokei} \texttt{NENC,_ENDIAN,BITS}

Given an IOS descriptor, a bit-offset and an integer value of \texttt{BITS} bits, poke it. Use the negative encoding and endianness specified in the instruction arguments.

In case of an error, this instruction pushes an exception describing the error condition. Otherwise it pushes PVM\_NULL.

Stack: ( INT ULONG INT -- EXCEPTION\|null )
27.1.28.11 Instruction pokeiu
Synopsys:

\[
\text{pokeiu ENDIAN,BITS}
\]

Given an IOS descriptor, a bit-offset and an unsigned integer value of BITS bits, poke it. Use the endianness specified in the instruction arguments.

In case of an error, this instruction pushes an exception describing the error condition. Otherwise it pushes PVM_NULL.

Stack: ( INT ULONG INT -- EXCEPTION|null )

27.1.28.12 Instruction pokel
Synopsys:

\[
pokel NENC,ENDIAN,BITS
\]

Given an IOS descriptor, a bit-offset and a long value of BITS bits, poke it. Use the negative encoding and endianness specified in the instruction arguments.

In case of an error, this instruction pushes an exception describing the error condition. Otherwise it pushes PVM_NULL.

Stack: ( INT ULONG LONG -- EXCEPTION|null )

27.1.28.13 Instruction pokelu
Synopsys:

\[
pokelu ENDIAN,BITS
\]

Given an IOS descriptor, a bit-offset and an unsigned long value of BITS bits, poke it. Use the endianness specified in the instruction arguments.

In case of an error, this instruction pushes an exception describing the error condition. Otherwise it pushes PVM_NULL.

Stack: ( INT ULONG ULONG -- EXCEPTION|null )

27.1.28.14 Instruction pokedi
Synopsys:

\[
pokedi BITS
\]

Given an IOS descriptor, a bit-offset and an integer of BITS bits, poke it. Use the default negative encoding and endianness.

In case of an error, this instruction pushes an exception describing the error condition. Otherwise it pushes PVM_NULL.

Stack: ( INT ULONG INT -- EXCEPTION|null )

27.1.28.15 Instruction pokediu
Synopsys:

\[
pokediu BITS
\]

Given an IOS descriptor, a bit-offset and an unsigned integer of BITS bits, poke it. Use the default endianness.

In case of an error, this instruction pushes an exception describing the error condition. Otherwise it pushes PVM_NULL.

Stack: ( INT ULONG UINT -- EXCEPTION|null )
27.1.28.16 Instruction pokedl

Synopsys:

\[ \text{pokedl BITS} \]

Given an IOS descriptor, a bit-offset and a long of BITS bits, poke it. Use the default negative encoding and endianness.

In case of an error, this instruction pushes an exception describing the error condition. Otherwise it pushes PVM_NULL.

Stack: \((\text{INT ULONG LONG} \rightarrow \text{EXCEPTION|null})\)

27.1.28.17 Instruction pokedlu

Synopsys:

\[ \text{pokedlu BITS} \]

Given an IOS descriptor, a bit-offset and an unsigned long of BITS bits, poke it. Use the default endianness.

In case of an error, this instruction pushes an exception describing the error condition. Otherwise it pushes PVM_NULL.

Stack: \((\text{INT ULONG ULONG} \rightarrow \text{EXCEPTION|null})\)

27.1.28.18 Instruction peeks

Synopsys:

\[ \text{peeks} \]

Given an IOS descriptor and a bit-offset, peek a string.

If there is a problem performing the operation, this function pushes an exception in the stack. Otherwise, it pushes the peeked value and PVM_NULL.

Stack: \((\text{INT ULONG} \rightarrow \text{[STR] EXCEPTION|null})\)

27.1.28.19 Instruction pokes

Synopsys:

\[ \text{pokes} \]

Given an IOS descriptor, a bit-offset and a string, poke it.

In case of an error, this instruction pushes an exception describing the error condition. Otherwise it pushes PVM_NULL.

Stack: \((\text{INT ULONG STR} \rightarrow \))

27.1.29 Exceptions handling instructions

27.1.29.1 Instruction pushe

Synopsys:

\[ \text{pushe LABEL} \]

Given an Exception struct in the stack, push a handler for it on the exceptions stack. An exception code 0 means any exception.

Stack: \((\text{EXCEPTION} \rightarrow \))

Exception Stack: \((\rightarrow \text{EXCEPTION\_HANDLER})\)
27.1.29.2 Instruction pope

Synopsys:

\[
pope
\]
Pop an exception handler from the exceptions stack.
Stack: ( -- )
Exception Stack: ( EXCEPTION_HANDLER -- )

27.1.29.3 Instruction raise

Synopsys:

\[
raise
\]
Raise the given exception.
Stack: ( EXCEPTION -- )
Exception Stack: ( -- )

27.1.29.4 Instruction popexite

Synopsys:

\[
popexite
\]
Pops the exception on the stack and sets it in the VM.
Stack: ( EXCEPTION -- )
Exception Stack: ( -- )

27.1.30 Debugging Instructions

27.1.30.1 Instruction strace

Synopsys:

\[
strace \text{ DEPTH}
\]
Print a debugging trace with the elements of the top of the stack. The number of elements to print is specified in DEPTH. A depth of zero means to print the whole stack.
Stack: ( -- )

27.1.30.2 Instruction rtrace

Synopsys:

\[
rtrace \text{ DEPTH}
\]
Print a debugging call trace. The number of elements to print is specified in DEPTH. A depth of zero means to print the whole call trace.
Stack: ( -- )

27.1.30.3 Instruction disas

Synopsys:

\[
disas
\]
Print out the disassembling of the program executed by the closure in the top of the stack.
Stack: ( CLS -- CLS )
27.1.30.4 Instruction note
Synopsys:

\[ \text{note\ VALUE} \]

This instruction is intended to be used to insert annotations that help to understand disassemblies. Most of the times VALUE is a string.

Semantically, this instruction does nothing.
Stack: ( -- )

27.1.30.5 Instruction vmdisp
Synopsys:

\[ \text{vmdisp} \]

Pushes the current dispatching strategy of current VM to the stack.
Stack: ( -- STR )

27.1.31 System Interaction Instructions

27.1.31.1 Instruction getenv
Synopsys:

\[ \text{getenv} \]

This instruction gets the name of an environment variable on the stack and pushes the value of the corresponding environment variable. If no variable with the given name is defined on the environment, then push PVM_NULL.

Stack: ( STR -- STR STR )

27.1.32 Miscellaneous Instructions

27.1.32.1 Instruction nop
Synopsys:

\[ \text{nop} \]

Do nothing.
Stack: ( -- )

27.1.32.2 Instruction rand
Synopsys:

\[ \text{rand} \]

Push a pseudo-random integer to the stack.
If the argument is 0U then it is ignored. Otherwise it is used to set the seed for a new sequence of pseudo-random numbers.
Stack: ( UINT -- INT )

27.1.32.3 Instruction time
Synopsys:

\[ \text{time} \]

Push the current system time to the stack in the form of two long elements containing the number of seconds and nanoseconds since the epoch.
Stack: ( -- LONG(sec) LONG(nsec) )
27.1.32.4 Instruction sleep

Synopsys:

```
sleep
```
Sleep for a given number of seconds and nanoseconds.
If the provided number of nanoseconds are not in the range 0 to 999999999 or the number of provided seconds is negative, pushes -1.
If there is any other error performing the operation then push -2.
EINTR is treated as no error currently.
Stack: ( LONG LONG -- LONG LONG INT )

27.1.32.5 Instruction siz

Synopsys:

```
siz
```
Given a value, push its size as a bit-offset. By convention, the following PVM values have size zero: type, closure, null
Stack: ( VAL -- VAL ULONG )

27.1.32.6 Instruction sel

Synopsys:

```
sel
```
Given a value, push its length as an unsigned long.
The length of an array is the number of values contained in it. The length of a struct is the number of fields contained in it. The length of a string is the number of characters contained in it. The length of any other value is 1.
Stack: ( VAL -- VAL ULONG )

Appendix B GNU Free Documentation License

Version 1.3, 3 November 2008

http://fsf.org/

Everyone is permitted to copy and distribute verbatim copies of this license document, but changing it is not allowed.

0. PREAMBLE

The purpose of this License is to make a manual, textbook, or other functional and useful document free in the sense of freedom: to assure everyone the effective freedom to copy and redistribute it, with or without modifying it, either commercially or noncommercially. Secondarily, this License preserves for the author and publisher a way to get credit for their work, while not being considered responsible for modifications made by others.

This License is a kind of “copyleft”, which means that derivative works of the document must themselves be free in the same sense. It complements the GNU General Public License, which is a copyleft license designed for free software.

We have designed this License in order to use it for manuals for free software, because free software needs free documentation: a free program should come with manuals providing the same freedoms that the software does. But this License is not limited to software manuals; it can be used for any textual work, regardless of subject matter or whether it is published as a printed book. We recommend this License principally for works whose purpose is instruction or reference.

1. APPLICABILITY AND DEFINITIONS

This License applies to any manual or other work, in any medium, that contains a notice placed by the copyright holder saying it can be distributed under the terms of this License. Such a notice grants a world-wide, royalty-free license, unlimited in duration, to use that work under the conditions stated herein. The “Document”, below, refers to any such manual or work. Any member of the public is a licensee, and is addressed as “you”. You accept the license if you copy, modify or distribute the work in a way requiring permission under copyright law.

A “Modified Version” of the Document means any work containing the Document or a portion of it, either copied verbatim, or with modifications and/or translated into another language.

A “Secondary Section” is a named appendix or a front-matter section of the Document that deals exclusively with the relationship of the publishers or authors of the Document to the Document’s overall subject (or to related matters) and contains nothing that could fall directly within that overall subject. (Thus, if the Document is in part a textbook of mathematics, a Secondary Section may not explain any mathematics.) The relationship could be a matter of historical connection with the subject or with related matters, or of legal, commercial, philosophical, ethical or political position regarding them.

The “Invariant Sections” are certain Secondary Sections whose titles are designated, as being those of Invariant Sections, in the notice that says that the Document is released under this License. If a section does not fit the above definition of Secondary then it is not allowed to be designated as Invariant. The Document may contain zero Invariant Sections. If the Document does not identify any Invariant Sections then there are none.

The “Cover Texts” are certain short passages of text that are listed, as Front-Cover Texts or Back-Cover Texts, in the notice that says that the Document is released under this License.
A Front-Cover Text may be at most 5 words, and a Back-Cover Text may be at most 25 words.

A “Transparent” copy of the Document means a machine-readable copy, represented in a format whose specification is available to the general public, that is suitable for revising the document straightforwardly with generic text editors or (for images composed of pixels) generic paint programs or (for drawings) some widely available drawing editor, and that is suitable for input to text formatters or for automatic translation to a variety of formats suitable for input to text formatters. A copy made in an otherwise Transparent file format whose markup, or absence of markup, has been arranged to thwart or discourage subsequent modification by readers is not Transparent. An image format is not Transparent if used for any substantial amount of text. A copy that is not “Transparent” is called “Opaque”.

Examples of suitable formats for Transparent copies include plain ASCII without markup, TeXinfo input format, LaTeX input format, SGML or XML using a publicly available DTD, and standard-conforming simple HTML, PostScript or PDF designed for human modification. Examples of transparent image formats include PNG, XCF and JPG. Opaque formats include proprietary formats that can be read and edited only by proprietary word processors, SGML or XML for which the DTD and/or processing tools are not generally available, and the machine-generated HTML, PostScript or PDF produced by some word processors for output purposes only.

The “Title Page” means, for a printed book, the title page itself, plus such following pages as are needed to hold, legibly, the material this License requires to appear in the title page. For works in formats which do not have any title page as such, “Title Page” means the text near the most prominent appearance of the work’s title, preceding the beginning of the body of the text.

The “publisher” means any person or entity that distributes copies of the Document to the public.

A section “Entitled XYZ” means a named subunit of the Document whose title either is precisely XYZ or contains XYZ in parentheses following text that translates XYZ in another language. (Here XYZ stands for a specific section name mentioned below, such as “Acknowledgements”, “Dedications”, “Endorsements”, or “History”.) To “Preserve the Title” of such a section when you modify the Document means that it remains a section “Entitled XYZ” according to this definition.

The Document may include Warranty Disclaimers next to the notice which states that this License applies to the Document. These Warranty Disclaimers are considered to be included by reference in this License, but only as regards disclaiming warranties: any other implication that these Warranty Disclaimers may have is void and has no effect on the meaning of this License.

2. VERBATIM COPYING

You may copy and distribute the Document in any medium, either commercially or noncommercially, provided that this License, the copyright notices, and the license notice saying this License applies to the Document are reproduced in all copies, and that you add no other conditions whatsoever to those of this License. You may not use technical measures to obstruct or control the reading or further copying of the copies you make or distribute. However, you may accept compensation in exchange for copies. If you distribute a large enough number of copies you must also follow the conditions in section 3.

You may also lend copies, under the same conditions stated above, and you may publicly display copies.

3. COPYING IN QUANTITY

If you publish printed copies (or copies in media that commonly have printed covers) of the Document, numbering more than 100, and the Document’s license notice requires Cover
Texts, you must enclose the copies in covers that carry, clearly and legibly, all these Cover Texts: Front-Cover Texts on the front cover, and Back-Cover Texts on the back cover. Both covers must also clearly and legibly identify you as the publisher of these copies. The front cover must present the full title with all words of the title equally prominent and visible. You may add other material on the covers in addition. Copying with changes limited to the covers, as long as they preserve the title of the Document and satisfy these conditions, can be treated as verbatim copying in other respects.

If the required texts for either cover are too voluminous to fit legibly, you should put the first ones listed (as many as fit reasonably) on the actual cover, and continue the rest onto adjacent pages.

If you publish or distribute Opaque copies of the Document numbering more than 100, you must either include a machine-readable Transparent copy along with each Opaque copy, or state in or with each Opaque copy a computer-network location from which the general network-using public has access to download using public-standard network protocols a complete Transparent copy of the Document, free of added material. If you use the latter option, you must take reasonably prudent steps, when you begin distribution of Opaque copies in quantity, to ensure that this Transparent copy will remain thus accessible at the stated location until at least one year after the last time you distribute an Opaque copy (directly or through your agents or retailers) of that edition to the public.

It is requested, but not required, that you contact the authors of the Document well before redistributing any large number of copies, to give them a chance to provide you with an updated version of the Document.

4. MODIFICATIONS

You may copy and distribute a Modified Version of the Document under the conditions of sections 2 and 3 above, provided that you release the Modified Version under precisely this License, with the Modified Version filling the role of the Document, thus licensing distribution and modification of the Modified Version to whoever possesses a copy of it. In addition, you must do these things in the Modified Version:

A. Use in the Title Page (and on the covers, if any) a title distinct from that of the Document, and from those of previous versions (which should, if there were any, be listed in the History section of the Document). You may use the same title as a previous version if the original publisher of that version gives permission.

B. List on the Title Page, as authors, one or more persons or entities responsible for authorship of the modifications in the Modified Version, together with at least five of the principal authors of the Document (all of its principal authors, if it has fewer than five), unless they release you from this requirement.

C. State on the Title page the name of the publisher of the Modified Version, as the publisher.

D. Preserve all the copyright notices of the Document.

E. Add an appropriate copyright notice for your modifications adjacent to the other copyright notices.

F. Include, immediately after the copyright notices, a license notice giving the public permission to use the Modified Version under the terms of this License, in the form shown in the Addendum below.

G. Preserve in that license notice the full lists of Invariant Sections and required Cover Texts given in the Document’s license notice.

H. Include an unaltered copy of this License.

I. Preserve the section Entitled “History”, Preserve its Title, and add to it an item stating at least the title, year, new authors, and publisher of the Modified Version as given
on the Title Page. If there is no section Entitled “History” in the Document, create one stating the title, year, authors, and publisher of the Document as given on its Title Page, then add an item describing the Modified Version as stated in the previous sentence.

J. Preserve the network location, if any, given in the Document for public access to a Transparent copy of the Document, and likewise the network locations given in the Document for previous versions it was based on. These may be placed in the “History” section. You may omit a network location for a work that was published at least four years before the Document itself, or if the original publisher of the version it refers to gives permission.

K. For any section Entitled “Acknowledgements” or “Dedications”, Preserve the Title of the section, and preserve in the section all the substance and tone of each of the contributor acknowledgements and/or dedications given therein.

L. Preserve all the Invariant Sections of the Document, unaltered in their text and in their titles. Section numbers or the equivalent are not considered part of the section titles.

M. Delete any section Entitled “Endorsements”. Such a section may not be included in the Modified Version.

N. Do not retitle any existing section to be Entitled “Endorsements” or to conflict in title with any Invariant Section.

O. Preserve any Warranty Disclaimers.

If the Modified Version includes new front-matter sections or appendices that qualify as Secondary Sections and contain no material copied from the Document, you may at your option designate some or all of these sections as invariant. To do this, add their titles to the list of Invariant Sections in the Modified Version’s license notice. These titles must be distinct from any other section titles.

You may add a section Entitled “Endorsements”, provided it contains nothing but endorsements of your Modified Version by various parties—for example, statements of peer review or that the text has been approved by an organization as the authoritative definition of a standard.

You may add a passage of up to five words as a Front-Cover Text, and a passage of up to 25 words as a Back-Cover Text, to the end of the list of Cover Texts in the Modified Version. Only one passage of Front-Cover Text and one of Back-Cover Text may be added by (or through arrangements made by) any one entity. If the Document already includes a cover text for the same cover, previously added by you or by arrangement made by the same entity you are acting on behalf of, you may not add another; but you may replace the old one, on explicit permission from the previous publisher that added the old one.

The author(s) and publisher(s) of the Document do not by this License give permission to use their names for publicity for or to assert or imply endorsement of any Modified Version.

5. COMBINING DOCUMENTS

You may combine the Document with other documents released under this License, under the terms defined in section 4 above for modified versions, provided that you include in the combination all of the Invariant Sections of all of the original documents, unmodified, and list them all as Invariant Sections of your combined work in its license notice, and that you preserve all their Warranty Disclaimers.

The combined work need only contain one copy of this License, and multiple identical Invariant Sections may be replaced with a single copy. If there are multiple Invariant Sections with the same name but different contents, make the title of each such section unique by adding at the end of it, in parentheses, the name of the original author or
publisher of that section if known, or else a unique number. Make the same adjustment to
the section titles in the list of Invariant Sections in the license notice of the combined work.
In the combination, you must combine any sections Entitled “History” in the various original
documents, forming one section Entitled “History”; likewise combine any sections Entitled
“Acknowledgements”, and any sections Entitled “Dedications”. You must delete all sections
Entitled “Endorsements.”

6. COLLECTIONS OF DOCUMENTS
You may make a collection consisting of the Document and other documents released under
this License, and replace the individual copies of this License in the various documents with
a single copy that is included in the collection, provided that you follow the rules of this
License for verbatim copying of each of the documents in all other respects.
You may extract a single document from such a collection, and distribute it individually
under this License, provided you insert a copy of this License into the extracted document,
and follow this License in all other respects regarding verbatim copying of that document.

7. AGGREGATION WITH INDEPENDENT WORKS
A compilation of the Document or its derivatives with other separate and independent
documents or works, in or on a volume of a storage or distribution medium, is called an
“aggregate” if the copyright resulting from the compilation is not used to limit the legal
rights of the compilation’s users beyond what the individual works permit. When the
Document is included in an aggregate, this License does not apply to the other works in
the aggregate which are not themselves derivative works of the Document.
If the Cover Text requirement of section 3 is applicable to these copies of the Document,
then if the Document is less than one half of the entire aggregate, the Document’s Cover
Texts may be placed on covers that bracket the Document within the aggregate, or the
electronic equivalent of covers if the Document is in electronic form. Otherwise they must
appear on printed covers that bracket the whole aggregate.

8. TRANSLATION
Translation is considered a kind of modification, so you may distribute translations of the
Document under the terms of section 4. Replacing Invariant Sections with translations
requires special permission from their copyright holders, but you may include translations
of some or all Invariant Sections in addition to the original versions of these Invariant
Sections. You may include a translation of this License, and all the license notices in
the Document, and any Warranty Disclaimers, provided that you also include the original
English version of this License and the original versions of those notices and disclaimers. In
case of a disagreement between the translation and the original version of this License or a
notice or disclaimer, the original version will prevail.
If a section in the Document is Entitled “Acknowledgements”, “Dedications”, or “History”,
the requirement (section 4) to Preserve its Title (section 1) will typically require changing
the actual title.

9. TERMINATION
You may not copy, modify, sublicense, or distribute the Document except as expressly pro-
vided under this License. Any attempt otherwise to copy, modify, sublicense, or distribute
it is void, and will automatically terminate your rights under this License.
However, if you cease all violation of this License, then your license from a particular copy-
right holder is reinstated (a) provisionally, unless and until the copyright holder explicitly
and finally terminates your license, and (b) permanently, if the copyright holder fails to
notify you of the violation by some reasonable means prior to 60 days after the cessation.
Moreover, your license from a particular copyright holder is reinstated permanently if the
copyright holder notifies you of the violation by some reasonable means, this is the first
time you have received notice of violation of this License (for any work) from that copyright
holder, and you cure the violation prior to 30 days after your receipt of the notice.
Termination of your rights under this section does not terminate the licenses of parties
who have received copies or rights from you under this License. If your rights have been
terminated and not permanently reinstated, receipt of a copy of some or all of the same
material does not give you any rights to use it.

10. FUTURE REVISIONS OF THIS LICENSE
The Free Software Foundation may publish new, revised versions of the GNU Free Doc-
umentation License from time to time. Such new versions will be similar in spirit to the
present version, but may differ in detail to address new problems or concerns. See http://
www.gnu.org/copyleft/.
Each version of the License is given a distinguishing version number. If the Document
specifies that a particular numbered version of this License “or any later version” applies
to it, you have the option of following the terms and conditions either of that specified
version or of any later version that has been published (not as a draft) by the Free Software
Foundation. If the Document does not specify a version number of this License, you may
choose any version ever published (not as a draft) by the Free Software Foundation. If the
Document specifies that a proxy can decide which future versions of this License can be
used, that proxy’s public statement of acceptance of a version permanently authorizes you
to choose that version for the Document.

11. RELICENSING
“Massive Multiauthor Collaboration Site” (or “MMC Site”) means any World Wide Web
server that publishes copyrightable works and also provides prominent facilities for anybody
to edit those works. A public wiki that anybody can edit is an example of such a server. A
“Massive Multiauthor Collaboration” (or “MMC”) contained in the site means any set of
copyrightable works thus published on the MMC site.
“CC-BY-SA” means the Creative Commons Attribution-Share Alike 3.0 license published
by Creative Commons Corporation, a not-for-profit corporation with a principal place of
business in San Francisco, California, as well as future copyleft versions of that license
published by that same organization.
“Incorporate” means to publish or republish a Document, in whole or in part, as part of
another Document.
An MMC is “eligible for relicensing” if it is licensed under this License, and if all works that
were first published under this License somewhere other than this MMC, and subsequently
incorporated in whole or in part into the MMC, (1) had no cover texts or invariant sections,
and (2) were thus incorporated prior to November 1, 2008.
The operator of an MMC Site may republish an MMC contained in the site under CC-BY-
SA on the same site at any time before August 1, 2009, provided the MMC is eligible for
relicensing.
ADDENDUM: How to use this License for your documents

To use this License in a document you have written, include a copy of the License in the document and put the following copyright and license notices just after the title page:

Copyright (C) year your name.
Permission is granted to copy, distribute and/or modify this document under the terms of the GNU Free Documentation License, Version 1.3 or any later version published by the Free Software Foundation; with no Invariant Sections, no Front-Cover Texts, and no Back-Cover Texts. A copy of the license is included in the section entitled ``GNU Free Documentation License''.

If you have Invariant Sections, Front-Cover Texts and Back-Cover Texts, replace the "with...Texts." line with this:

with the Invariant Sections being list their titles, with the Front-Cover Texts being list, and with the Back-Cover Texts being list.

If you have Invariant Sections without Cover Texts, or some other combination of the three, merge those two alternatives to suit the situation.

If your document contains nontrivial examples of program code, we recommend releasing these examples in parallel under your choice of free software license, such as the GNU General Public License, to permit their use in free software.
